Status of Yellowtail Rockfish (*Sebastes flavidus*) Along the U.S. Pacific Coast in 2017

Contents

Executive Summary

executive-summary

Stock

stock

This assessment reports the status of the Yellowtail Rockfish (*Sebastes flavidus*) resource in U.S. waters off the coast of the California, Oregon, and Washington using data through 2016.

The Pacific Fishery Management Council (PFMC) manages the U.S. fishery as two stocks separated at Cape Mendocino, California (40° 10'N). The northern stock has long been assessed on its own; the southern stock is treated as part of the Southern Shelf Complex. This assessment analyzes each stock independently, with the southern stock extending southward to the U.S./Mexico border and the northern stock extending northward to the U.S./Canada border.

The most recent fully integrated assessment (Wallace and Lai 2005), following the pattern of prior assessments, included only the Northern stock which it divided into three assessment areas with divisions at Cape Elizabeth (47° 20'N) and Cape Falcon (45° 46'N). A data-moderate assessment conducted in 2013 (Cope et al. 2013) was the first to analyze the southern stock, determining its contribution to the overfishing limit (OFL) for the Southern Shelf Complex.

Since the 2005 assessment, reconstruction of historical catch by Washington and Oregon makes any border but the state line (roughly 46° N) incompatible with the data from those states. Additionally, much of the groundfish catch landed in northern Oregon is caught in Washington waters.

This assessment addresses the stock in two areas consistent with the management border at Cape Mendocino. This is consistent, as well, with a recent genetic analysis (Hess et al. n.d.) that found distinct stocks north and south of Cape Mendocino but did not find stock differences within the northern area.

Catches

catches

Catches from the Northern stock were divided into four categories: commercial catch, bycatch in the at-sea hake fishery, recreational catch in Oregon and California (north of 40° 10'N), and recreational catch in Washington. The first three of these fleets were entered in metric tons, but the recreational catch from Washington was entered in the model as numbers of fish with the average weight calculated internally in the model from the weight-length relationship and the length-compositions.

Catches from the Southern stock were divided into two categories: commercial and recreational catch, both of which were entered as metric tons.

Include: trends and current levels-include table for last ten years and graph with long term data

Data and Assessment

data-and-assessment

Include: date of last assessment, type of assessment model, data available, new information, and information lacking.

Yellowtail Rockfish was assessed north of Cape Mendocino in 2005 in a fully integrated age-based assessment. A 2013 data-moderate assessment was the first to address the southern stock (Cope et al. 2013).

This assessment uses Stock Synthesis version 3.3. The Northern model begins in 1889, with the assumption that the stock was at an unfished equilibrium that year? The Southern model begins in 1916, with the assumption that the stock was at an unfished equilibrium that year?

In this assessment, ecosystem considerations were. . . ..

Reference Points

reference-points

Include: management targets and definition of overfishing, including the harvest rate that brings the stock to equilibrium at $B_{40\%}$ (the B_{MSY} proxy) and the equilibrium stock size that results from fishing at the default harvest rate (the F_{MSY} proxy). Include a summary table that compares estimated reference points for SSB, SPR, Exploitation Rate and Yield based on SSBproxy for MSY, SPRproxy for MSY, and estimated MSY values

Write intro paragraph....and remove text for Models 2 and 3 if not needed

This stock assessment estimates that Yellowtail Rockfish in the Northern model are above the biomass target, but above the minimum stock size threshold. Add sentence about spawning output trend. The estimated relative depletion level for Model 1 in 2016 is 56.7% (~95% asymptotic interval: ± 45.4%-68.1%, corresponding to an unfished spawning output of 8.18588 trillion eggs (~95% asymptotic interval: 5.9-10.47 trillion eggs) of spawning output in the base model (Table i). Unfished age 4+ biomass was estimated to be 132.7 mt in the base case model. The target spawning output based on the biomass target ($SB_{40\%}$) is 5.8 trillion eggs, which gives a catch of 4116.9 mt. Equilibrium yield at the proxy F_{MSY} harvest rate corresponding to $SPR_{50\%}$ is 3882.8 mt.

This stock assessment estimates that Yellowtail Rockfish in the Southern model are above the biomass target, but above the minimum stock size threshold. Add sentence about spawning output trend. The estimated relative depletion level for Model 2 in 2016 is 98% (~95% asymptotic interval: ± 75.5%-120%), corresponding to an unfished spawning output of 5.68452 trillion eggs (~95% asymptotic interval:) of spawning output in the base model (Table j). Unfished age 4+ biomass was estimated to be 117.6 mt in the base case model. The target spawning output based on the biomass target ($SB_{40\%}$) is 2.3 trillion eggs, which gives a catch of mt. Equilibrium yield at the proxy F_{MSY} harvest rate corresponding to $SPR_{50\%}$ is 3136.4 mt.

This stock assessment estimates that Yellowtail Rockfish in the are

the biomass target, but
the minimum stock size threshold. Add sentence about spawning output trend. The estimated relative depletion level or Model 3 in 2016 is (~95% asymptotic interval: ±), corresponding to an unfished spawning output of (~95% asymptotic interval:) of spawning output in the base model (Table **??**). Unfished age 4+ biomass was estimated to be mt in the base case model. The target spawning output based on the biomass target ($SB_{40\%}$) is , which gives a catch of mt. Equilibrium yield at the proxy F_{MSY} harvest rate corresponding to $SPR_{50\%}$ is mt.

Research And Data Needs

research-and-data-needs

Include: identify information gaps that seriously impede the stock assessment.

We recommend the following research be conducted before the next assessment:

1. List item No. 1 in the list
2. List item No. 2 in the list, etc.

Rebuilding Projections

rebuilding-projections

Include: reference to the principal results from rebuilding analysis if the stock is overfished. This section should be included in the Final/SAFE version assessment document but is not required for draft assessments undergoing review. See Rebuilding Analysis terms of reference for detailed information on rebuilding analysis requirements.

1 Introduction

introduction

1.1 Basic Information

basic-information

Yellowtail rockfish, *Sebastes flavidus*, occur off the West Coast of the United States from Baja California to the Aleutian Islands. Yellowtail is a major commercial species, captured mostly in trawls from Central California to British Columbia (Love 2011). Because it is an aggregating, midwater species it is usually caught in the commercial midwater trawl fishery. In California there is a large recreational fishery as well. The center of yellowtail rockfish abundance is from southern Oregon through British Columbia (Fraidenburg 1980).

Once thought to comprise a single stock, a recent genetic study indicates that there are in fact two sub-species, with a genetic cline at Cape Mendocino, California, roughly 40°10′ North Latitude (Hess et al. n.d.). The species has never had a full length and age integrated assessment south of Cape Mendocino, mainly due to a lack of fishery-independent data; this assessment represents the first attempt to do so.

Yellowtail rockfish are colloquially known as "greenies", although *flavidus* is Latin for "yellow" (Love 2011). We have summarized yellowtail rockfish life history, fisheries, assessment and management here, but in-depth, extensive background information on yellowtail and other managed species is available at (Council 2016).

1.2 Map

map

A map showing the scope of the assessment and depicting boundaries for fisheries or data collection strata is provided in Figure **??**.

1.3 Life History

life-history

Rockfish are in general long-lived and slow-growing, however yellowtail rockfish have a high growth rate relative to other rockfish species, reaching a maximum size of about 55 cm in approximately 15 years (Tagart 1991). Yellowtail can live at least 64 years (Love 2011), however no fish that old occur in data available for this assessment (For the Northern model, the 95th percentile of age is 35 years for females and 45 years for males and for the Southern model, 30 and 40 years respectively for females and males). Yellowtail rockfish are among those that are fertilized internally and release live young. Spawning aggregations occur in the fall, and parturition in the winter and spring (January-May) (Eldridge et al. 1991). Young-of-the-year recruit to nearshore waters from April through August, migrating to deeper water in the fall. Preferred habitat is the midwater over reefs and boulder fields.

Yellowtail rockfish are extremely motile, and make rapid and frequent ascents and descents of 40 meters; they also exhibit strong homing tendencies (Love 2011). They are able to quickly release gas from their swim bladders, perhaps making them less susceptible to barotrauma than similar species (Eldridge et al. 1991).

Rockfish Conservation Areas (RCAs) have been closed to fishing since 2002. Following that closure, Yellowtail rockfish are among the many species that have been seen to increase in both abundance and in average size in Central California (Marks et al. 2015).

Literature values for von Bertallanfy parameters are $L_\infty = 52.2, k = 0.17, t_0 = -0.75$ for females, $L_\infty = 47.6, k = 0.19, t_0 = -1.69$ for males. Length-Weight parameters are $W = 0.0287L^{2.822}$ for females, $W = 0.0359L^{2.745}$ for males (Love 2011). These values were not those used in this assessment, however; the parameters are estimated in the models. See Section 2.3 for a discussion of the new analyses of the weight-length relationship used as priors for estimation. Fecundity is represented in the models as: $1.1185^{-11}W^{4.59}$. This is a rescaling of the values provided in (Dick et al. 2017).

1.4 Fishery and Management History

`fishery-and-management-history`

The rockfish fishery off the U.S. Pacific coast first developed off California in the late 19th century as a hook-and-line fishery (Love et al. 2002). The rockfish trawl fishery was established in the early 1940s, when the United States became involved in World War II and wartime shortage of red meat created an increased demand for other sources of protein (Harry and Morgan 1961, Alverson et al. 1964).

Until late 2002, yellowtail rockfish were harvested as part of a directed mid-water trawl fishery, with fairly high landings in the 1980s and 1990s. Yellowtail commonly co-occur with canary, widow rockfish and several other rockfishes (Tagart 1988); (Rogers and Pikitch 1992). Association with these and other rockfish species has substantially altered fishing opportunity for yellowtail rockfish since canary rockfish stocks were declared overfished by National Marine Fisheries service in 2000. In order to achieve the necessary reduction in the canary rockfish catch, stringent management measures were adopted, limiting harvest of yellowtail rockfish as well as other co-occurring species.

Beginning in 2000, shelf rockfish species could no longer be retained by vessels using bottom trawl footropes with a diameter greater than 8 inches. The use of small footrope gear increases the risk of gear loss in rocky areas. This restriction was intended to provide an incentive for fishers to avoid high-relief, rocky habitat, thus reducing the exposure of many depleted species to trawling. This was reinforced through reductions in landing limits for most shelf rockfish species.

Since September 2002, Rockfish Conservation Areas (RCAs, areas known to be critical habitat) have been closed to fishing. Alongside these closures, limits on landings have been in place that were designed so as to accommodate incidental bycatch only. These eliminated directed mid-water fishing opportunities for yellowtail rockfish in non-tribal trawl fisheries. A somewhat greater opportunity to target yellowtail rockfish in the trawl fishery has been available since 2011 under the trawl rationalization program, however quotas for widow and canary rockfish continue to constrain targeting of yellowtail rockfish. With the recent improved status of constraining stocks, the industry is developing strategies to better attain allocations of yellowtail and widow rockfish.

Yellowtail rockfish are currently managed with stock-specific harvest specifications north of 40°10′ N. latitude, and as part of the Southern Shelf Rockfish complex south of 40°10′ N. latitude. The Over Fishing Limit (OFL) contribution of yellowtail rockfish to the Southern Shelf Rockfish complex is based on a data-moderate analysis (Cope et al. 2013).

1.5 Assessment History

assessment-history

Early studies of yellowtail stocks on the U.S. West Coast north of 40°10′ N. latitude (Cape Mendocino, northern California) began in the 1980s with observational surveys. Statistical assessments of yellowtail rockfish were conducted in 1982 (Tagart 1982), 1988 (Tagart 1988), 1996 (Tagart et al. 1997), and 1997 (Tagart et al. 1997) to determine harvest specifications for the stock. These early assessments employed a variety of statistical methods, for example, the 1997 assessment used cohort analysis and dynamic pool modeling. Figure 53shows the timeseries of age 4+ biomass for Yellowtail Rockfish across past assessments.

The yellowtail assessment in 2000 (Tagart et al. 2000) was the first that estimated stock status, with an estimated depletion of 60.5 percent at the start of 2000. Lai et al. (Lai et al. 2003) updated the 2000 assessment and estimated that stock depletion was 46 percent at the start of 2003. A second assessment update was prepared in 2005 (Wallace and Lai 2005) with an estimated depletion of 55 percent at the start of 2005. The 2000 assessment and updates were age-structured assessments conducted using AD Model Builder as the software platform for nonlinear optimization (Fournier et al. 2012).

A data-moderate assessment of yellowtail rockfish south of 40°10′ N. latitude was conducted in 2013 (Cope et al. 2013). This assessment estimated depletion at the start of 2013 at 67 percent, and estimated the spawning biomass at 50,043 mt. This was a large biomass increase relative to previous estimates and may be attributed to the low removals over the previous decade.

Include: Management performance tables comparing Overfishing Limit (OFL), Annual Catch Limit (ACL), Harvest Guideline (HG) [CPS only], landings, and catch (i.e., landings plus discard) for each area and year.

Management performance table: (Table k)

A summary of these values as well as other base case summary results can be found in Table o.

1.6 Fisheries off Canada, Alaska, and/or Mexico

fisheries-off-canada-alaska-andor-mexico

The 2015 Stock Assessment conducted by the Department of Fisheries and Oceans (DFO) found the stock to be at 0.49B0, in the "healthy" range.

The Alaska Fisheries Science Center assesses yellowtail rockfish as one of 25 species in the "Other Rockfish" complex in the Gulf of Alaska. The 2015 full assessment of this complex found no evidence of overfishing, which is confirmed in the 2016 SAFE document(Center 2016).

Limited catches of yellowtail are reported as far south as Baja California(Love 2011).

2 Data

data

Data used in the Northern and Southern yellowtail rockfish assessments are summarized in Figures 58 and 58.

Data sources for the two models are largely distinct. Northern fisheries and surveys had very sparse data (if any) for the south and vice-versa. Among the 12 data sources referenced below, only 2 data sources are common to both models. These are the MRFSS/RecFIN recreational dockside survey, which focuses on California and Oregon, and the CalCOM California commercial dataset, which contributed data from the northern-most California counties (Eureka and Del Norte) to the Northern model. The CalCOM data account for less than five percent of the commercial landings in the Northern model, and less than 1% of the biological samples.

Commercial landings are not differentiated in either model. For the Northern model, this is due to the very small portion (1.15 %) of the landings that are attributed to non-trawl gear. For the Southern model, this is due to the paucity of data.

A description of each model's data sources follows.

2.1 Northern Model Data

northern-model-data

Summary of the data sources in the Northern model.

2.1.1 Commercial Fishery Landings

commercial-fishery-landings

Washington and Oregon Landings The bulk of the commercial landings for Washington and Oregon came from the from the Pacific Fisheries Information Network (**PacFIN**) database.

Washington Catch Information
The Washington Department of Fisheries and Wildlife (**WDFW**) provided historical yellowtail catch for 1889–1980. Landings for 1981-2016 came from the PacFIN database. WDFW also provided catches for the period 1981 – 2016 to include the re-distribution of the unspeciated "URCK" landings in PacFIN; this information is currently not available from PacFIN.

Oregon Catch Information
The Oregon Department of Fisheries and Wildlife (**ODFW**) provided historical yellowtail catch from 1892-1985. ODFW also provided estimates of yellowtail rockfish in the in the un-speciated PacFIN "URCK" and "POP1" catch categories for recent years, and those estimates were combined with PacFIN landings for 1986-2016.

Northern California Catch
The California Commercial Fishery Database (**CalCOM**) provided landings for the Northern model for the two counties north of $40°10'$ (Eureka and Del Norte) for 1969-2016.

Hake Bycatch
The Alaska Fisheries Science Center (**AFSC**) provided data for yellowtail bycatch in the hake fishery from 1976-2016.

2.1.2 Sport Fishery Removals

sport-fishery-removals

Washington Sport Catch
WDFW provided recreational catches for 1967 and 1975-2016.

Oregon Sport Catch
ODFW provided recreational catch data for 1979-2016.

MRFSS and RecFIN Data from Northern California came from the Marine Recreational Fisheries Statistical Survey (**MRFSS**) and from the Recreational Fisheries Information Network (**RecFIN**). These are dockside surveys focused on California and Oregon. MRFSS was conducted from 1980-1989 and 1993-2003, RecFIN from 2004 to the present.

2.1.3 Estimated Discards

estimated-discards

Commercial Discards

The West Coast Groundfish Observing Program (**WCGOP**) is an onboard observer program that has extensively surveyed fishing practices since 2002, with nearly 100% observer coverage in the trawl sector in recent years. WCGOP provided discard ratios for yellowtail rockfish from 2002 to 2015.

Pikitch Study

The Pikitch study was conducted between 1985 and 1987 (Pikitch et al. 1988). The northern and southern boundaries of the study were 48°42′ N latitude and 42°60′ N. latitude respectively, which is primarily within the Columbia INPFC area (Pikitch et al. 1988 , Rogers and Pikitch 1992).

Participation in the study was voluntary and included vessels using bottom, midwater, and shrimp trawl gears. Observers of normal fishing operations on commercial vessels collected the data, estimated the total weight of the catch by tow and recorded the weight of species retained and discarded in the sample.

Pikitch study discards were aggregated due to small sample size and included in the data as representing a single year mid-way through the study.

2.1.4 Abundance Indices

abundance-indices

Commercial Logbook CPUE

The commercial logbook (fish-ticket) data in PacFIN was used to generate an index for the years 1987-1998, a period in which management of the fishery was stable, i.e., regulations weren“t changing fishery practices.

The data were modeled with a modified Stephens-MacCall approach (Stephens and MacCall 2004). This approach uses the species composition of the catch to evaluate the per-haul probability of encountering a particular species; in this case, yellowtail rockfish. The intent of the analysis is to eliminate all hauls from the index that could not encounter yellowtail.

Usually, the Stephens-MacCall approach is a simple binomial model for presence-absence of the predictive species and the target, however a generalized linear mixed-effects approach – modeling the species as binomial and adding random effects for the interaction of year and vessel, for haul duration, and for month improved the model fit.

The hauls identified with a reasonable probability of encountering yellowtail were then modeled in a delta-lognormal glm to produce an annual index of abundance, bootstrapped 500 times to evaluate uncertainty.

Hake Bycatch Index

The Hake bycatch data provided by the Alaska Fisheries Science Center (AFSC) was used to generate an index of abundance for 1985-1999.

Data on haul-by-haul catch of Yellowtail Rockfish and Pacific Hake for the period 1976-2016 were obtained from the At-Sea Hake Observer Program along associated information including the location of each tow and the duration. Previous Yellowtail assessments used an index of abundance for the years 1978-1999. The most recent assessment (Wallace and Lai, 2005) stated that the index was not updated to include years beyond 1999 "because subsequent changes in fishery regulations and behavior have altered the statistical properties of these abundance indices". The ending year of 1999 was retained for this analysis. However, the years up to 1984 have relatively few tows with adequate information for CPUE analysis, and fishing effort off the coast of Washington where yellowtail are most commonly encountered (Figure 12). Therefore, for this new analysis, 1985 was chosen as the starting year.

The hake fishery was evolving during the chosen 15 year period (1985-1999), which included a transition from foreign to domestic fleets fishing for Pacific Hake (Figure 13). The index from the at-sea hake fishery used in previous assessments standardized for changes in catchability by using a ratio estimator relating yellowtail catch to hake catch and then scaling by an estimate of fishing effort for hake (Equation 1 in Wallace and Lai, 2005). However, that approach does not take into account differences in the spatial distribution of the at-sea hake fishery relative to the distributions of hake and yellowtail.

For this new analysis, changes in catchability were estimated by comparing an index based on a geostatistical analysis of the hake CPUE from VAST (Thorson et al. YYYY) to the estimated available hake biomass from the most recent stock assessment (Berger et al. 2017). The relative catchability was then used to adjust an independent geostatistical index of yellowtail CPUE (Figure 14). In order to capture the general trend in catchability, reducing the variability among years, linear, exponential, and locally smoothed (LOWESS) models were fit to the time series of individual estimates of hake index to available biomass (lower panel in Figure 14). Of these, the LOWESS model best captured the pattern of fastest change in the middle of the time series. The average rate of increase in the resulting estimated catchability time series is 13% per year.

VAST was then used to conduct a geostatistical standardization of the CPUE of yellowtail caught as bycatch in the at-sea hake fishery. The resulting yellowtail index after adjustment by the estimated changes in catchability is qualitatively more similar to the index used in previous assessments (Figure 15) than the index resulting from assuming constant catchability.

2.1.5 Fishery-Independent Data

fishery-independent-data

Northwest Fisheries Science Center (NWFSC) shelf-slope survey

This survey, referred to as the **NWFSCcombo Survey**, has been conducted annually starting in 2003. It uses a random-grid design covering the coastal waters from a depth of 55 m to 1,280 m from late-May to early-October (add reference: Bradburn 2011). Four chartered industry vessels are used each year (with the exception of 2013 when the U.S. federal government shutdown curtailed the survey).

The data from the NWFSCcombo survey was analyzed using a spatio-temporal delta-model (add reference: Thorson2015), implemented as an R package VAST (add reference: Thorson2017) and publicly available online (https://github.com/James-Thorson/VAST). Spatial and spatio-temporal variation is specifically included in both encounter probability and positive catch rates, a logit-link for encounter probability, and a log-link for positive catch rates. Vessel-year effects were included for each unique combination of vessel and year in the database.

Both lognormal and gamma distributions were explored for the positive tows and produced similar results with the lognormal model showing better patterns in Q-Q plot. The index shows variability with an overall gradual increase from 2003 to 2013 with high estimates near the end of the time series in 2014 and 2016. A design-based index extrapolated from swept area densities without any geostatistical standardization shows a more dramatic increase from 2015 to 2016.

Length and age compositions were also developed from this survey.

Alaska Fisheries Science Center (AFSC) Triennial shelf survey

The **Triennial Survey** was conducted by the AFSC every third year between 1977 and 2001, (and was conducted in 2004 by the NWFSC using the same protocols). The 1977 survey had incomplete coverage and is not believe to be comparable to the later years. The survey design used equally-spaced transects from which searches for tows in a specific depth range were initiated. The depth range and latitudinal range was not consistent across years, but all years in the period 1980-2004 included the area from 40° 10'N north to the Canadian border and a depth range that included 55-366 meters, which spans the range where the vast majority of Yellowtail encountered in all trawl surveys. Therefore the index was based on this depth range.

An index of abundance was estimated based on the VAST delta-GLMM model as described for the NWFSCcombo Index above. In this case as well, Q-Q plots indicated slightly better performance of the lognormal over gamma models for positive tows. The index shows a gradual decline from 1980 to 1992 followed by high variability in the final 4 points spanning 1995-2004.

2.1.6 Biological Samples

biological-samples

Length And Age Compositions

Length composition data were compiled from PacFIN for Oregon and Washington for the Northern model and combined with raw (unexpanded) length data from CalCOM for the two California counties north of 40° 10'N (Eureka and Del Norte counties).

Length compositions were provided from the following sources:

Summary of the time series of lengths used in the stock assessment.

tab:Length_sources

Source	Type	Lengths	Tows	Years
PacFIN	commercial	186161	3830	1968-2016

2.2.1 Commercial Fishery Landings

commercial-fishery-landings-1

California Commercial Landings
The California Commercial Fishery Database (**CalCOM**) provided landings in California south of 40° 10'N for 1969-2016.

Historical Data A reconstruction of the historical commercial fishery south of Cape Mendocino was provided by the Southwest Fisheries Science Center (**SWFSC**) for 1916-1968.

2.2.2 Sport Fishery Removals

sport-fishery-removals-1

MRFSS Estimates and RecFIN
The California Department of Fish and Wildlife (**CDFW**) provided estimated yellowtail removals for the Marine Recreational Fisheries Statistical Survey (**MRFSS**) from 1980-1989, 1993-2003. The Recreational FIsheries Information Network, (**RecFIN**) provided landings for 2004-2016.

Historical Data A reconstruction of the historical recreational fishery south of Cape Mendocino was provided by the Southwest Fisheries Science Center (**SWFSC**) for 1928-1980.

Small Research Study A small number of fish were collected from the recreational fishery by the SWFSC and are included in the data for 1978-1984.

2.2.3 Estimated Discards

estimated-discards-1

No discard data were available for the Southern model.

2.2.4 Abundance Indices

abundance-indices-1

MRFSS Index

An index of abundance was developed from trip-aggregated MRFSS data for the years 1980-1989, 1992-2003.

California Onboard Survey

An Onboard recreational survey conducted by provided data for an index of abundance provided by the SWFSC for 1987-2016.

Research Study Index An index of abundance for the small juvenile fish research study was provided by the SWFSC for 2001-2016.

2.2.5 Fishery-Independent Data

fishery-independent-data-1

Hook and Line Survey

The NWFSC Hook and Line survey provided data for an index in the Southern California Bight from 2004-2016.

2.2.6 Biological Samples

biological-samples-1

Length composition samples were available for the Southern model from 5 sources, and ages from 3.

Length compositions were provided from the following sources:

Summary of the time series of lengths used in the stock assessment.

tab:Length_sources

2.3 Biological Parameters Common to Both Models

bio-params
biological-parameters-common-to-both-models

Aging Precision And Bias

Age error matrices were developed for double-reads at the PFMC aging lab in Newport, OR and for double reads within the WDFW aging lab. The Newport lab has done all of the Survey aging for the NWFSC, along with some commercial ages and the 400 fish from the Small Study. WDFW provided the bulk of recreational and commercial ages. Between-lab differences in aging were minute, as were within-lab differences. This result is supported by the primary age reader's assessment: yellowtail rockfish are extremely easy to age (B. Kamikawa, pers. comm.).

Weight-Length

The weight-length relationship is based on the standard power function: $W = \alpha(L^{\beta})$ where W is individual weight (kg), L is length (cm), and α and β are coefficients used as constants.

To estimate this relationship, 12,778 samples with both weight and length measurements from the fishery independent surveys were analyzed. These included 6,354 samples from the NWFSC Combo survey, 5,085 from the Triennial survey, and 1,339 from the Hook and Line survey. All Hook and Line survey samples were from the Southern area, along with 910 samples from the other two surveys (Figure 4).

A single weight-length relationship was chosen for females and males in both areas after examining various factors that may influence this relationships, including sex, area, year, and season. None of these factors had a strong influence in the overall results. Season was one of the bigger factors, with fish sampled later in the year showing a small increase in weight at a given length (2-6% depending on the other factors considered). However, season was confounded with area because most of the samples from the Southern area were collected from the Hook and Line survey which takes place later in the year (mid-September to mid-November) and the resolution of other data in the model do not support modeling the stock at a scale finer than a annual time step.

Males and females did not show strong differences in either area, and the estimated differences were in opposite directions for the two areas, suggesting that this might be a spurious relationship or confounded with differences timing of the sampling relative to spawning.

The estimated coefficients resulting from this analysis were $\alpha = 1.1843e-05$ and $\beta = 3.0672$.

Maturity And Fecundity Maturity was estimated from histological analysis of

141 samples collected in 2016. These include 96 from the NWFSC Combo survey, 25 from mid-water catches in the NWFSC acoustic/trawl survey, 13 from the Hook and Line survey,

and 7 from Oregon Department of Fish and Wildlife. The sample sizes were not adequate to estimate differences in maturity by area. Length at 50% maturity was estimated at 42.49cm (Figure **??**) which was consistent with the range 37-45cm cited in the previous assessment (Wallace and Lai 2005).

Natural Mortality Natural Mortality priors were provided by Owen Hamel (pers. comm.). See Section 3.2.5 for further discussion.

Sex ratios

The largest fish seen in the data are females, however the oldest are males. The sex ratio falls off differently in each model, as can be seen in Figs(x,y).

2.3.1 Environmental Or Ecosystem Data Included In The Assessment

environmental-or-ecosystem-data-included-in-the-assessment

No environmental index is present in either model.

3 Assessment

assessment

3.1 History Of Modeling Approaches Used For This Stock

history-of-modeling-approaches-used-for-this-stock

Yellowtail rockfish was previously modeled as ag age-structured, 3-area stock north of $40^\circ 10'$ in 1999 (Tagart et al. 2000) using a model written in ADMB (Fournier et al. 2012); an update of this assessment was last conducted in 2004 (Wallace and Lai 2005). That assessment divided the stock into 3 INPFC areas which are not coincident with state boundaries; this is a concern in that recent reconstructions of historical catch are state-by-state along the West Coast. Because we cannot produce data that conform to the areas previously assessed, we have made no effort to reproduce the previous model.

A data-moderate approach was used to evaluate stock status in 2013 (Cope et al. 2013). This approach is not compatible with the current model, and we have made no attempt to reproduce it.

3.1.1 Previous Assessment Recommendations

previous-assessment-recommendations

Many of the recommendations of the previous STAR panel are not relevant to this assessment, as they related to data deficiencies at that time that have since been resolved. The 2004 STAR particularly recommended a focus on abundance indices, which they noted might require further survey information.

This assessment provides four indices for the Northern model, and three for the Southern model. All indices are newly developed for this analysis.

3.2 Model Description

model-description

3.2.1 Transition To The Current Stock Assessment

transition-to-the-current-stock-assessment

These are the main changes from the previous model, and our rationale for them:

1. Transition to Stock Synthesis. *Rationale*: The Pacific Fishery Management Council's preferred modeling platform for stock assessments is Stock Synthesis (Methot 2015), developed since the last full assessment of yellowtail rockfish.
2. Addition of Southern model. *Rationale*: Hess, et al. determined that the West Coast yellowtail stocks show a genetic cline occurring near Cape Mendocino, which is roughly $40°10'$ north latitude (Hess et al. n.d.). This divides the stock into two genetically distinct substocks which we model independently.
3. Availability of recent data. *Rationale*: Ten years of data collection have occurred since the last update assessment, and the data necessary for an assessment of the Southern stock is now available.
4. Historical catch reconstructions. *Rationale*: Reconstruction of catch timeseries in California, Washington and Oregon clarify stock history as far back as 1889.

3.2.2 Definition of Fleets and Areas

definition-of-fleets-and-areas

The Northern model comprises the area between Cape Mendocino, California, and the Canadian border. The Southern model runs from Cape Mendocino to the Mexican border 2

Northern Model

Commercial: The commercial fleet consists primarily of bottom and midwater trawl. No attempt was made to analyze the fishery separately by gear, particularly since it seems that in the fishery in the 1980s and 1990s, "bottom trawl" gear was used in the midwater as well as on the bottom, and "midwater gear" was sometimes dragged across soft bottom (Craig Goode, ODFW Port Sampler, pers. comm).

The data associated with the commercial fleet includes age- and length-composition data from PacFIN and CalCOM, historical catch timeseries from CDFW, ODFW and WDFW. Observations of discards from the Pikitch research study provide lengths and discard rates; discard lengths and rates calculated from WCGOP data. Sex was available for the comps in the retained catch, which is by-sex in the model, but was not available for the discards, so they are undifferentiated by sex.

The PacFIN logbook (fish ticket) index developed for the commercial fishery is in fish/tow. Further information about how the data for the index was worked up is in Appendix **??**.

At-Sea Hake Fishery: Yellowtail Rockfish are frequently caught in mid-water trawls associated with the At-Sea Hake Fishery (consisting of the Catcher-Processor and Mothership sectors). These catches are recorded and biological sampling takes place but the fish are processed at sea (typically into fish meal) and are not included in the PacFIN database, so this fishery requires separate analysis. The At-Sea Hake fishery provides catches, length compositions by sex, and an index of abundance.

Recreational: The recreational fleet includes data from sport fisheries off Oregon, and northern California (Eureka and Del Norte counties), from MRFSS and RecFIN. The index of abundance for the recreational fleet is in fish per angler-hour. Length data for this fleet are undifferentiated by sex.

Washington-Sport: The Washington data (WA_Sport) provides catches, lengths and ages, and was treated as a separate fleet for two reasons: first, the length composition of the Washington catches were different from those in the recreational landings in Oregon and northern California (MRFSS/RecFIN data). There are very large fish in this dataset, and fewer small ones. Second, the WA_Sport landings are not available by weight, so they are entered in the model as numbers, andStock Synthesis internally converts them to weight using the combination of estimated selectivity for this fleet (informed by the length compositions), estimated growth, and the weight-length relationship. Sex was available for the biological data, however many lengthed fish were not sexed, so the lengths for this fleet are undifferentiated by sex, although the ages are.

Research: The Alaska Fisheries Science Center's Triennial Trawl survey, provides age- and length-compositions, and an index of abundance. This survey was conducted every third year from 1977-2004. Details on the workup of the CPUE (in biomass/area towed) can be found in Appendix **??**.

The Northwest Fisheries Science Center's NWFSCcombo survey provides age- and length-compositions, as well as an index of abundance. Details on the workup of the CPUE (in biomass/area towed) can be found in Appendix **??**.

Conditional Age-at-Length: Only the NWFSCcombo ages were used as conditional age-at-length in the model. All other aged fleets (Commercial, Washington_Sport, and Triennial) are present in the model as marginal ages due to the amount of noise in the age data for those fleets.

Indices: Fish per angler-hour is the basis for the Washington_Sport and Pikitch indices. The NWFSCcombo and Triennial surveys provide indices based on biomass per area-towed. The logbook survey for the commercial fleet is in units of fish per tow.

Southern Model

Commercial: The commercial fleet consists primarily of hook and line and trawl gear. Hook and line gear account for 78% of the landings by weight in the recent period (1978-2016). Commercial data were sexed, although there are many unsexed lengths. To preserve the large numbers of lengths, the length data are entered in the model as undifferentiated, however the ages are sexed and provide the sole conditional age-at-length timeseries in the Southern Model.

Recreational: The recreational fleet includes data from sport fishery off the California coast south of Cape Mendocino. The recreational lengths are unsexed. The index is in fish per angler_hour. Further information about how the index was worked up is in Appendix **??**.

California Onbord Recreational Survey: Research derived-data include observations from the California Onboard recreational survey. The length-compositions from this survey are undifferentiated by sex. The index is in fish per angler_hour.

NWFSC Hook-and-Line Survey: The data from this survey are used in the model as an index of fish per angler_hour, a single year of marginal age data by sex, and sexed length compositions.

Small Fish Study: A separate index, length comps and a single year of ages reflect a small study of juvenile fish conducted by the SWFSC.

3.2.3 Modeling Software

`modeling-software`

The STAT team used Stock Synthesis 3 (Methot 2015), which is the Pacific Fishery Management Council's preferred modeling platform for assessments.

3.2.4 Data Weighting

`data-weighting`

Commercial and survey length composition and marginal age composition data are weighted according to the method of Ian Stewart (pers.comm):

Sample Size = 0.138 * Nfish + Ntows if Nfish/Ntows < 44, and Ntows * 7.06 otherwise.

Age-at-Length samples are unwieghted; that is, each fish is assumed to represent an independent sample.

Recreational trips (the analogue of tows in the commercial fishery) are difficult to define in most cases. Since much of the recreational data are from the dockside interview MRFSS program, which didn't anticipate the need to delineate samples as belonging to particular trips, we chose to use all recreational data "as-is", with the initial weights entered as number of fish.

Weighting among fleets uses either the Francis method (Francis 2011) or the Ianelli-McAllister harmonic mean method (McAllister and Ianelli 1997). The Francis method was used for all fleets, except for the age data from the Southern model's Hook and Line survey, which is a single year of data to which we applied the Ianelli-McAllister method.

3.2.5 Priors priors

priors

Hamel (Hamel 2015) developed a method for combining meta-analytic approaches to relating the natural mortality rate M to other life-history parameters such as longevity, size, growth rate and reproductive effort, to provide a prior on M. In that same issue of ICESJMS, Then et al. (Then et al. 2014), provided an updated data set of estimates of M and related life history parameters across a large number of fish species, from which to develop an M estimator for fish species in general. They concluded by recommending M estimates be based on maximum age alone, based on an updated Hoenig non-linear least squares estimator $M = 4.899A_{max}^{-.916}$.

The approach of basing M priors on maximum age alone was one that was already being used for west coast rockfish assessments. However, in fitting the alternative model forms relating M to Amax, Then et al. did not consistently apply their transformation. In particular, in real space, one would expect substantial heteroscedasticity in both the observation and process error associated with the observed relationship of M to Amax. Therefore, it would be reasonable to fit all models under a log transformation. This was not done.

Re-evaluating the data used in Then et al. (Then et al. 2014) by fitting the one-parameter Amax model under a log-log transformation (such that the slope is forced to be -1 in the transformed space (as in Hamel 2015)), the point estimate for M is $M = 5.4/Amax$

This is also the median of the prior. The prior is defined as a lognormal with mean lna(5.4/Amax) and SE = 0.4384343.

Natural mortality priors for these models were based on examination of the 99% quantile of the observed ages from early in the time-series, before the full impact of fishing would have taken place. For the Northern model, these quantiles were approximately 35 years for females and 45 years for males, resulting in median M values of 0.15 and 0.12 for females and males. For the Southern model, the 99% quantile of the early age observations were approximately 30 and 40 years for females and males, resulting in median M prior values of 0.18 and 0.135, respectively. In both models, M for males was represented as an offset from females. In the Northern model, both the female value and the male offset could be estimated without priors so the priors were not used. For the southern model, M was fixed at the median prior values for the two sexes.

The prior for steepness (h, 0.718) was provided by James Thorson and used as a fixed parameter in both models. need citation

3.2.6 General Model Specifications

general-model-specifications

Fecundity is represented in the models as: $1.1185^{-11}W^{4.59}$. This is a rescaling of the values provided in (Dick et al. 2017).

Model data, control, starter, and forecast files can be found at https://DEVORE

3.2.7 Estimated And Fixed Parameters

estimated-and-fixed-parameters

A full list of all estimated and fixed parameters is provided in Tables.... Estimated and fixed parameters tables currently read in from .csv file, EXAMPLE: Table **??**

3.3 Model Selection and Evaluation

model-selection-and-evaluation

3.3.1 Key Assumptions and Structural Choices

key-assumptions-and-structural-choices

Selectivity in both models is asymptotic, with the exception of the OR-CA MRFSS recreational fleet in the Northern model, and the Onboard recreational fleet in the Southern model.

For the Northern model, several options for developing a CPUE series for the recreational fishery were considered but rejected as sparse and noisy. Similarly, the Washington_Sport fishery data was evaluated a a possible source for an index, but the data was not available in a form useful for a recreational index, i.e., there was no data that provided for a trip-level analysis of catch and effort, as was used for the MRFSS index in the Southern model (Stephens and MacCall 2004).

3.3.2 Alternate Models Considered

alternate-models-considered

Time-blocked selectivity and retention were investigated in the Northern model, as were domed selectivities.

We also explored time-blocks on selectivity in the Southern model, and domed selectivity for the MRFSS/RecFIN data.

These approaches resulted in model fits to data that were obviously poor, and so they were rejected

3.3.3 Convergence

convergence

Convergence testing through use of dispersed starting values often requires extreme values to explore new areas of the multivariate likelihood surface. Stock Synthesis provides a jitter option that generates random starting values from a normal distribution logistically transformed into each parameter's range (Methot 2015). We used this function to find parameter values for convergence in the Southern model. The Northern model report jittering when it's been done.

3.4 Response To The Current STAR Panel Requests

`response-to-the-current-star-panel-requests`

Request No. 4: Example of a request that may have a list:

- **Item No. 1**
- **Item No. 2**
- **Item No. 3, etc.**

Rationale: Add after STAR panel.

STAT Response: Continue requests as needed.

3.5 Life History Results for both models

life-history-results-for-both-models

Maturity in the model was estimated outside the model at the Northwest Fisheries Science Center by Melissa Head, and is shown in Figure 3.

Figure 4 shows the results of the analysis of the Weight-Length relationship estimated and used as fixed input for both models.

The growth at the beginning of the year estimated by the models for the Northern and Southern stocks is shown in Figure 5. Females grow faster in each case, but the Northern stock grows faster and attains larger maximum size.

3.6 Northern Model Base Case Results

northern-model-base-case-results

The data used in the Northern model by fishery is shown in Figure 58. Estimated catches are shown in Figure 7; estimated discards are in Figure 8. These show the large catches in the 1980s and 90s are being predicted by the model. The large discards in latter years match the data well for those years.

The timeseries of estimated spawning output in units? is shown in Figure{fig:ssb}. The model is estimating two periods of decline, one beginning in the forties and a steeper decline in the 1970s and 1980s, followed by an increase since 2000 to pre-1980 levels. There is a decrease in the final years of the timeseries coincident with increased uncertainty.

Figure 86 shows the total biomass following a similar pattern; the ending value is value metric tonnes.

The spawning depletion (Figure 87) went below the 40% target in the early 1980s, and may have been below the minimum stock size limit of 25% in the late 1990s, but has rebounded since to value (see Table **??**).

Figures 88 and 89 address recruitments estimated the the model. The first of these shows the age-0 recruits, and the second the recruitment deviations. Ian? What do we want to say about these?. The stock-recruit curve, Figure 90 shows a shallow relationship between stock size and recruitment with an asymptote at larger stock sizes.

3.6.1 Selectivities, Indices and Discards

selectivities-indices-and-discards

Selectivities in the Northern model (Figure 60) shows the difference between the recreational fisheries and the commercial fishery and survey sampling. All of the fish are fully selected by 50 cm, but the recreational fish are fully selected at 30 cm.

Retention by length (Figure ??) varies over time between 40% and 100%, with no clear pattern of interannual variation, except for the trawl-rationalization era 2011-present.

Discarding in the commercial fleet (Figure 11) is fit only by putting blocks on retention in the Northern model. Discards were very low except during the 1990s and 2000s, until the trawl-rationalization program implementation.

Fits to the indices for the northern model (Figure ??) demonstrate the utility of the NWFSC-combo survey. Although the model misses the uptick at the end of the timeseries, it is the only recent index and is well-fit by the model. The other indices are noisier. Most of the indices are fairly flat, indicating little change in abundance during each time-period. Although the fit to the Triennial index is poor, the data nicely reflects the changes in management during it's tenure: the CPUE was falling during the 1980s and 1990s, then rising after stringent restrictions began in 2000.

3.6.2 Lengths

`lengths`

Bubble plots for the lengths in the fishery (Figure 17) show the constancy of the commercial fleet, and the differences in growth between males and females; the females are larger, the males smaller. The recreational fleet is represented by two different sampling regimes, and the changeover in the mid-2000s is clear in that panel. That the WA_Sport fishery catches larger fish is represented in the large bubbles at the top of the panel. Had we examined that fishery earlier in the process of putting the model together, we might have settled on a larger maximum size bin, however that fishery remains the smallest portion of the catches.

Commercial length comps are very well fit (Figures ?? and ??). Commercial discards are noiser and not well fit (Figure ??). The panel describing the combined fits and data weighting for the commercial fishery is duplicted, need to remove redundant figure.

Lengths in the early period of the Hake Bycatch fishery are noisy (doubtless due to small sample sizes). By 1992, the model is able to fit the data well (Figure ??). Figure ?? shows that the fits in the early period have twice (at last) the uncertainty of the later period.

The recreation OR+N.CA timeseries of lengths demonstrates the difference between the MRFSS sampling and RecFIN sampling. The fits in the early period are good, those in the later period are noisy and model uncertainty is high (Figures ?? and ??).

The WA_Sport length fits might have been improved with a better choice of maximum size bin for the model (Figures ?? and ??), however the data are noisy throughout the size range represented.

The Trinnial lengths Figures ?? and 30 are fit well in some years and not in others. The data is not noisy, however the intermittency of data collection may mean that the model is unable to capture interannual variation as well as for an annual timeseries.

NWFSCcombo lengths are not well fit, particularly in 2013, where the data show a large number of small fit that may represent a good recruitment several years earlier Figures **??** and **??**.

Figure 33 shows the relative fits among the data sources, aggregated across time. The timeseries of presence-absence residuals indicated by filled- and open-bubbles Figure 34 and Figure 35 demonstrates the relative disappointment in model fits; the smaller the bubble, the better the match between the data and the model expectation.

3.6.3 Ages

ages

The NWFSCcombo survey provided the only source of conditional age-at-length data for the Northern model; ages for other fleets were treated as marginal ages.

The fits to the marginal commercial Figure **??** are quite good from about 1979 on, even fitting the tail where the ages beyond 55 are lumped. The weightings panel Figure **??** shows the same thing: fits are good after about 1979, and the decrease in mean age in the population corresponds with high catches in the 1980s and 1990s, with mean age increasing after 2000 as catches were curtailed.

The Washington Sport ages are noisy, and the fit is poor throughout the timeseries, see Figure **??** and Figure **??**.

The Triennial ages are noisy but are fit surprisingly well **??**; 41. That the model misses the influx of young fish in 1986 may be due to the timing of the survey; three-year surveys may not provide enough data for the model to fit recruitment events.

Aggregated age comps for the Commercial, Washington Sport and Triennial fleets are shown in Figure 42, for comparison. Agreggated fits for the Commercial and Triennial fleets are very satisfying.

The Ghost age comps Figure **??** for the NWFSCcombo survey are the marginal age comps for the survey aggregated over length. This figure is included for informational purposes only; the marginal "ghost" comps are not included in the likelihood calculations. It is interesting that the model fits this aggregated data poorly, but the disaggregated data well. This may be due to the fact that for marginal ages, the data are weighted interannually with number of tows or trips, but this ghost fleet is unweighted.

Pearson residuals for the marginal age comps, are shown in the bubble plots in Figure **??**. The filled bubbles represent estimates greater than observations, and the open bubbles observations greater than estimates. The large filled bubbles at age 25 in a few years suggest that we might have chosen a slightly older age as the compilation age.

The fits to the length-aggregate NWFSCcombo data show more variation in mean age in the population in latter years than might be expected in years with relatively low landings Figure **??**. These may represent young fish recruiting to the fishery, which would happen approximately 5 years after a biological recruitment event. The conditional age-at-length fits are shown in Figure 46. These plots explain the reason this survey was chosen to represent conditional age-at-length; the model was able to fit these data much better than other datasets, and improved fit, lower likelihood values and increased parsimony all contributed to a better model.

3.7 Northern Model Parameters

`northern-model-parameters`

For the Base model, the parameter fits are given in Table **??**. Status for all of the estimated parameters is good, with the exception of the 6th parameter for the selectivity in the Washington Sport fishery.

3.7.1 Northern Model Uncertainty and Sensitivity Analyses

`section`

Table 4

3.7.2 Northern Model Retrospective Analysis

`northern-model-retrospective-analysis`

3.7.3 Northern Model Likelihood Profiles

`northern-model-likelihood-profiles`

We profiled the change in negative log likelihood for the data sources and model total likelihood for critical parameters in the model: **R0**, the log of equilibrium recruitment; female natural mortality, **MF**; male natural mortality, **MM**; and steepness, **h**, the parameter that reflects how quickly the stock-recruit relationship allows the stock to rebound from depleted stock size.

The likelihood profile over a range of values (from 9 to 11) R0 are shown in Figure 54. This plot shows the tension between the index data and the other data sources. The indices are better fit with a smaller value of R0, near 9.6, while all other data sources are better fit at larger values. The overall likelihood in the model is lowest at 10.3 in this figure. The discards show very little change (are insensitive) over this range of R0, while the recruitments, ages and lengths are all minimized at values larger than 10.5.

The likelihood profile over female natural mortality, MF, is over a range from 0.1 to 0.24 (Figure 55). In this figure, the indices are fit best when MF is 0.1, the ages and lengths are fit nearer 0.18, and the recruitments and total log likelihoods are minimized at 0.15.

Figure 56 shows the likelihood profile for male natural mortality, MM, over a range of negative values that are the offset from female mortality (FM). The index data are again at odds with the other data sources; all but the indices are minimized at a value of -0.15. Male natural mortality is represented as an offset from that for females based on the equation $MM = MF * exp(offset)$, such that an offset of 0 results in equal mortality for males and females, and an offset of -0.3 results in a male natural mortality which is about 74% of the female mortality ($exp(-0.3) = 0.7408$).

The profile over values of steepness, h, from 0.5 to 0.9, Figure 57, shows the index data for once in the majority as all data sources except the lengths support 0.9 as minimizing the likelihood, while the lengths support a value closer to 0.5. The scale of this plot differs from the others; it is roughly a tenth of the scale of the R0 plot, meaning that the choice of h within this range has far less impact on likelihood in the model than choices for the other profiled parameters. This suggests the stock is not depleted; the choice of steepness would have a much greater impact on a depleted stock.

3.7.4 Northern Model Reference Points

`northern-model-reference-points`

Intro sentence or two. . . .(Table 5).

Equilibrium yield at the proxy F_{MSY} harvest rate corresponding to $SPR_{50\%}$ is

Knit kept whining about missing ref pts table, wouldn't work, took out ref.

shows the full suite of estimated reference points for the northern area model and Figure i shows the equilibrium yield curve.

3.8 Southern Model Base Case Results
southern-model-base-case-results

Data used in the Southern model is shown in Figure 58.

One thing to point out is that although the scale of the biomass in the model is somewhat sensitive to various data sources, the depletion is not. In tuning the model we were suprised to note that depletion always stayed above 80%.

Estimated catches are shown in Figure 59.

The estimated spawning biomass in Figure 85 shows the size of the uncertainty in this model. Total biomass (Figure 86) shows a sharp upward trend in recent years, the decade with only one year of age data from the Hook-and-Line Survey. Spawning depletion has sinuous curves and was likely never as low as the 40% target, even in the 1980s-1990s (Figure 87.

Recruitments have been constant, except 2008 and 2010, when the model sees extra large recruitments with extra large recruitment deviations (Figures 88 and 89). The spawner-recruit curve, Figure 90 is a line.

3.8.1 Southern Model Selectivities, Indices and Discards
southern-model-selectivities-indices-and-discards

Selectivity by fleet is shown in Figure 60. Selectivities for all but the recreational Onboard fishery are modeled as asymptotic; both recreational fleets (MRFSS/RecFIN and Onboard) are fully selected at 30cm; the remaining fleets show full selectivity at 45-50 cm.

Index fits leave something to be desired. All are more-or-less flat, with all of the three current indices, the Onboard, the Juvenile study and the Hook-and-Line survey all missing a downturn at the end of the timeseries. During model tuning, we tried introducing a time-blocked index for the two periods of the Onboard survey, however it didn't improve the fit to the index significantly, and increased the (negative log) likelihood of the model.

There was little information to inform the Southern Model of discard behavior, except in the Onboard survey, where it was represented by extremely small numbers. We included these discards in the retained fishery, since attempts to include it as a type-1 "retained plus discards" fishery prevented the model from converging.

3.8.2 Southern Model Lengths
southern-model-lengths

Lengths in the Southern model were entered as unsexed, except for the Hook-and-Line fishery. There were sexes for the Commercial lengths, however there were also large numbers of unsexed lengths, and we chose to model the lengths as unsexed, to include as much of the data as possible. This was true of the Small-Fish study, as well.

Bubble plots of the lengths by year in each fishery are in Figure 62. The plot for the recreational fishery clearly shows the transition from the MRFSS sampling program to RecFIN in 2003/2004, as well as suggesting the existence of larger fish in the 1980s. The Commercial fishery data has been sparse in recent years, however the fish taken in the Commercial catch are consistently larger than those in the recreational fishery, no doubt reflecting trawling in deeper waters. The Onboard survey lengths reflect two eras of sampling, again with larger fish in the earlier period. The panel for the Hook-and-Line survey shows that the females landed are always larger than the males, in agreement with the model estimates of growth: Figure 5.

The fits to the lengths in the Recreational fishery Figure **??** show variable fits through the years, with the noisy and sparse data in 2004 heralding the transition between MRFSS sampling and RecFIN. Overall, the timeseries is fit fairly well: Figure **??**

The Commercial length comps are fit well through 2005, when data becomes sparse and noisy Figure **??**; and Figure **??**.

Fits for the Onboard Survey lengths are good in the early survey, and poor for the later period **??**; **??**. Attempting to apply a time-block to this data resulted in poor convergence.

The Hook-and-Line Survey lengths are noisy (Figure **??**), but the fits are acceptable, and follow the trend of the data better than those for the other datasets: Figure **??**.

The small fish survey lengths are not fit badly **??**; **??**, and it is perhaps a shame that there are so few years to this timeseries.

The aggregate fits to the length comps for all five datasets is shown in Figure 73, and Pearson residuals for the lengths in Figure 74. Filled bubbles represent under-estimation of the data, open bubbles represent overestimation.

3.8.3 Southern Model Ages

`southern-model-ages`

There are few marginal ages in the model. Bubble plots for the Southern model ages (Figure **??**) show the small sample from the Juvenile Fish Study and the single year of ages from the Hook-and-Line Survey. The samples are too small to show any inter-annual variation, and are noisy within-year.

Figure **??** shows the fit to the Juvenile Fish samples, which is poor in all four years. The mean age in this data is shown in Figure **??**, at 10 years.

The Hook-and-Line Survey age "fit" is shown in Figure **??**. Mean age could not be calculated for the single year of data, as it is a inter-annual mean.

The aggregated fits for the marginal, and I *do* mean *marginal* ages are shown in Figure 80. They speak for themselves.

The ghost fleet commercial comps aggregated as a marginal timeseries is shown in Figure **??**. This figure is included for informational purposes only; ghosts do not contribute to the model likelihood calculations. The fits here are quite good 1981-1999, however the last three years of data are very sparse and not well fit.

Pearson residuals for the Small Fish Juvenile Study and the Hook-and-Line Survey are shown in Figure 82. Bubble size indicates the amount of disappointment in the fits. The filled bubbles indicate underestimates by the model; the open bubbles indicate overestimates.

The good news age-data comes from the commercial fleet, as was foreshadowed by the ghost fleet. Figure **??** shows the interannual fits to the mean age in the commercial age-at-length data. Except for 1981, 1982 and 1989, the model is able to fit the data reasonably well, detecting the downward trend in the late 1980s and into the mid-1990s.

The annual plots of age-at-length fits (Figure 84) show good fits in all years except 2001-2002 ("the sparse years, when we had to eat Gefilte-miltz").

3.8.4 Southern Model Uncertainty and Sensitivity Analyses

`southern-model-uncertainty-and-sensitivity-analyses`

3.8.5 Southern Model Retrospective Analysis

`southern-model-retrospective-analysis`

3.8.6 Southern Model Likelihood Profiles

`southern-model-likelihood-profiles`

We profiled the change in negative log likelihood for the data sources and model total likelihood for critical parameters fixed in the model: **R0**, the log of equilibrium recruitment; female natural mortality, **MF**; male natural mortality, **MM**; and steepness, **h** the parameter that reflects how quickly the stock-recruit relationship allows the stock to rebound from depleted stock size.

The likelihood profile for **R0** is shown in Figure 91. R0 was profiled over values from 8.5 -11. The figure shows that the age data and indices are minimized when R0 is 11; the length data are minimized around 8.5, and the recruitments at 9.8 (or so). The overall likelihood is minimized near 10.5.

The female natural mortality (FM) profile, 92 ranges from 0.1 to 0.24. The age and length data sources are at odds over FM; the ages and recruitments are minimized when FM is the low end of the range, and the lengths and indices when it is highest. Changes to the recruitment likelihood is minimal over the whole range. The overall likelihood is minimized near 0.22.

Male natural mortality (MM) is profiled over a range from -0.4 to 0. Male natural mortality is represented as an offset from that for females based on the equation $MM = MF * exp(offset)$, such that an offset of 0 results in equal mortality for males and females, and an offset of -0.3 results in a male natural mortality which is about 74% of the female mortality ($exp(-0.3) = 0.7408$). All roads lead to Rome in this figure (Figure 93); since all data sources and the overall likelihood are minimized at zero. Likelihoods for recruitments and indices are flat over the range of MM; the other data sources show changes of 20 (lengths) and 80 (ages) likelihood values.

The steepness profile (Figure 94is the most colorful, as the lines bounce around and change direction, however the likelihood scale is from 0 to 0.7, meaning that none of the values in this range (0.5 - 0.9) would have much impact on likelihood in the model. This supports the conclusion that the stock is abundant. For a depleted stock, steepness would have a very large impact on the likelihood.

5 Regional Management Considerations

regional-management-considerations

Management of the yellowtail rockfish northern stock has always been delineated by the 40° 10' line and the Canadian border. That the stock's genetic cline was found at Cape Mendocino is a happy accident that reinforces 40° 10' as the appropriate management line.

This assessment was not designed to test that choice. Given that the data for commercial and recreational fisheries is collected by the individual states (WA, OR, CA), it might have been interesting to investigate a management line at the California/Oregon border, had the STAT team the time and managers the interest in investigating a change.

6 Research Needs

research-needs

1. A longer timeseries of the juvenile rockfish CPUE in the south.

2. A commercial index in the north. This is by far the largest segment of the fishery, and the introduction of trawl rationalization program should mean that an index can be developed for the current fishery when the next assessment is performed.

3. More recent ages for the southern model. The commercial age timeseries currently stops in 2002.

9 Figures

figures

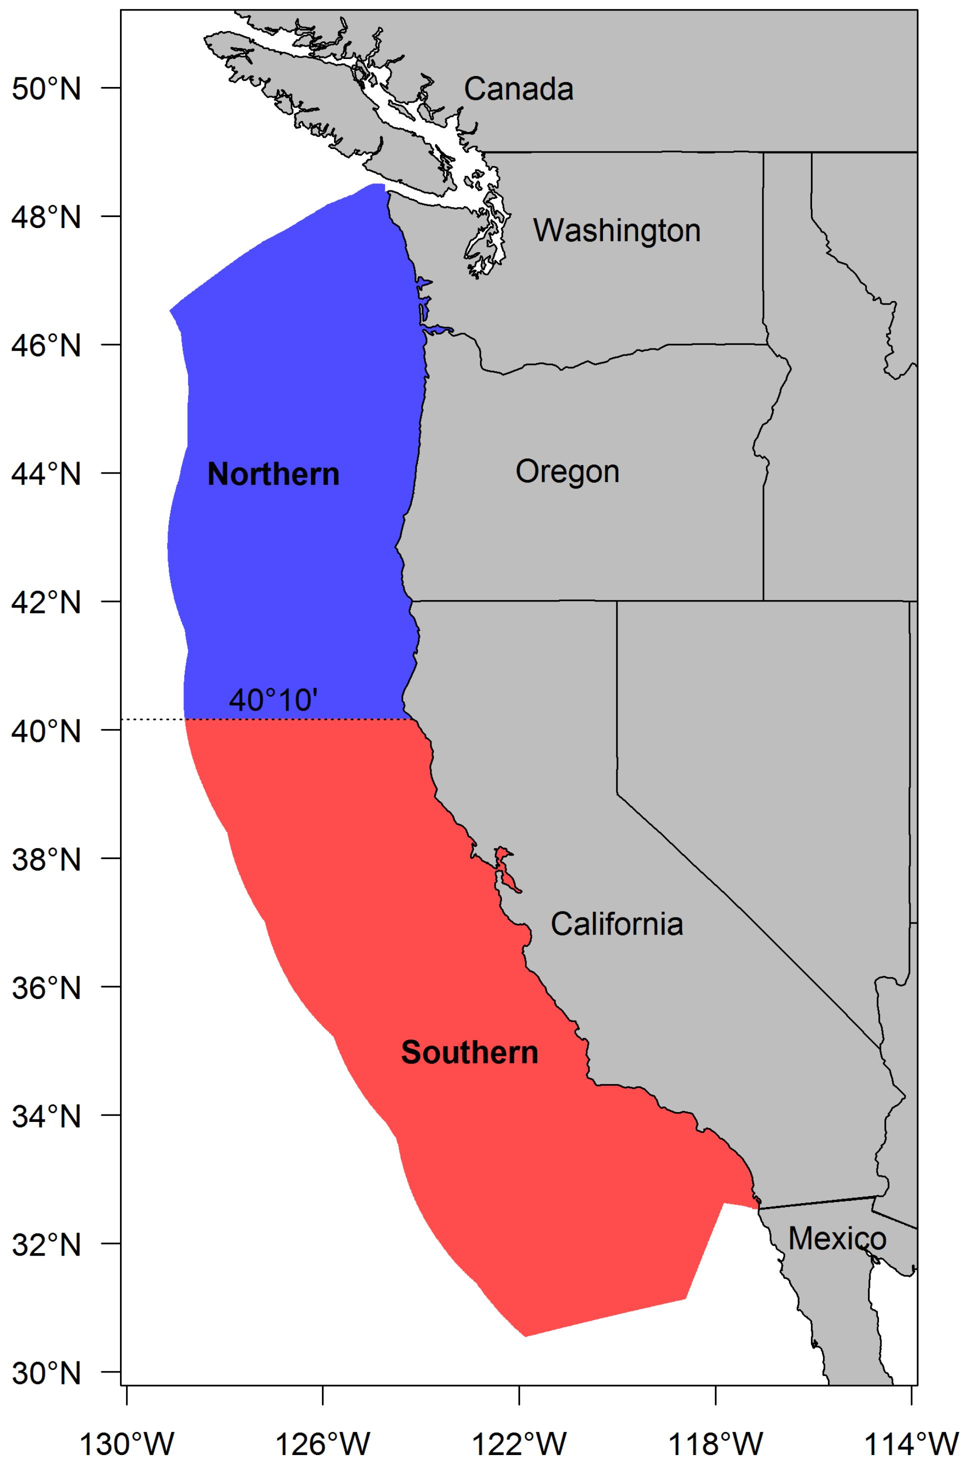

Figure 1: Map depicting the boundaries for the base-case model. fig:assess_region_map

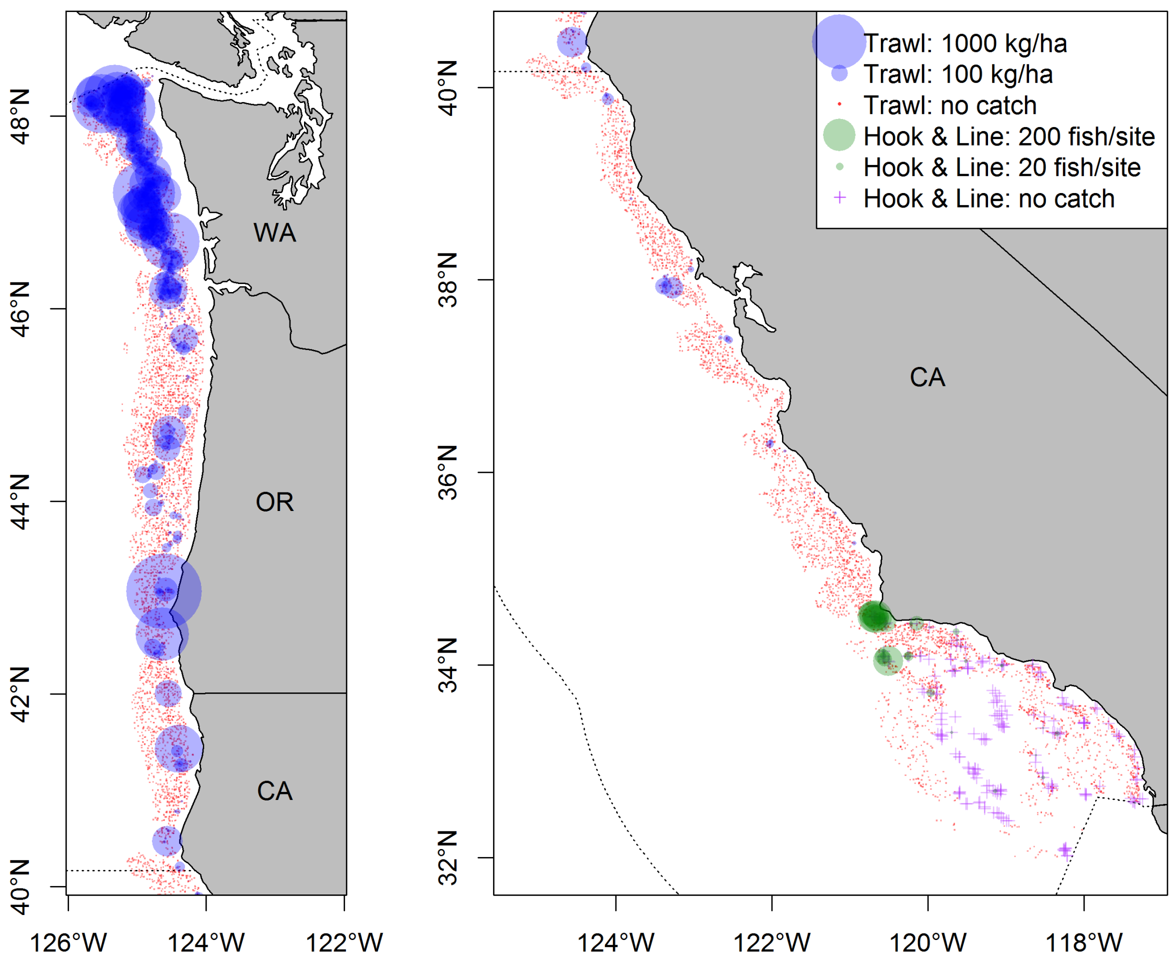

Figure 2: Map showing observations of Yellowtail Rockfish in the NWFSCcombo trawl survey and Hook & Line survey. fig:assess_region_map

9.1 Life history (maturity, fecundity, and growth) for both models

life-history-maturity-fecundity-and-growth-for-both-models

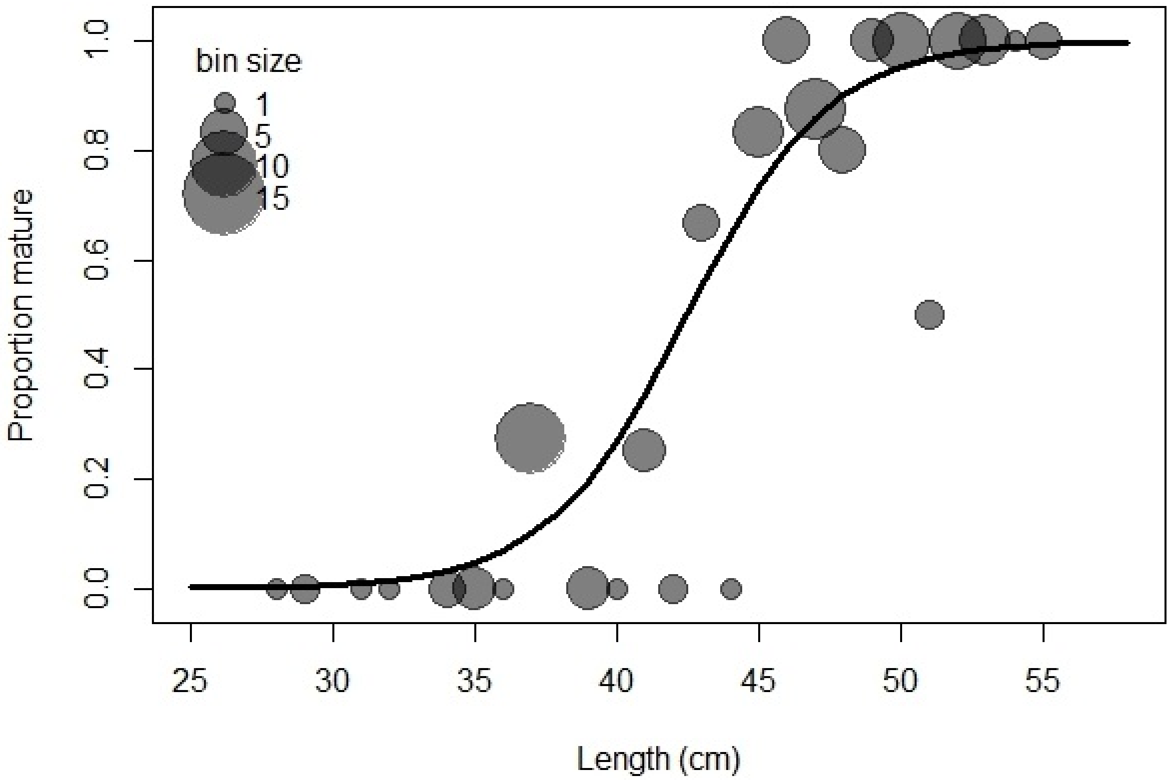

Figure 3: Estimated maturity relationship for Yellowtail Rockfish used in both models. Gray points indicate average observed functional maturity within each length bin with point size proportional to the number of samples. fig:maturity

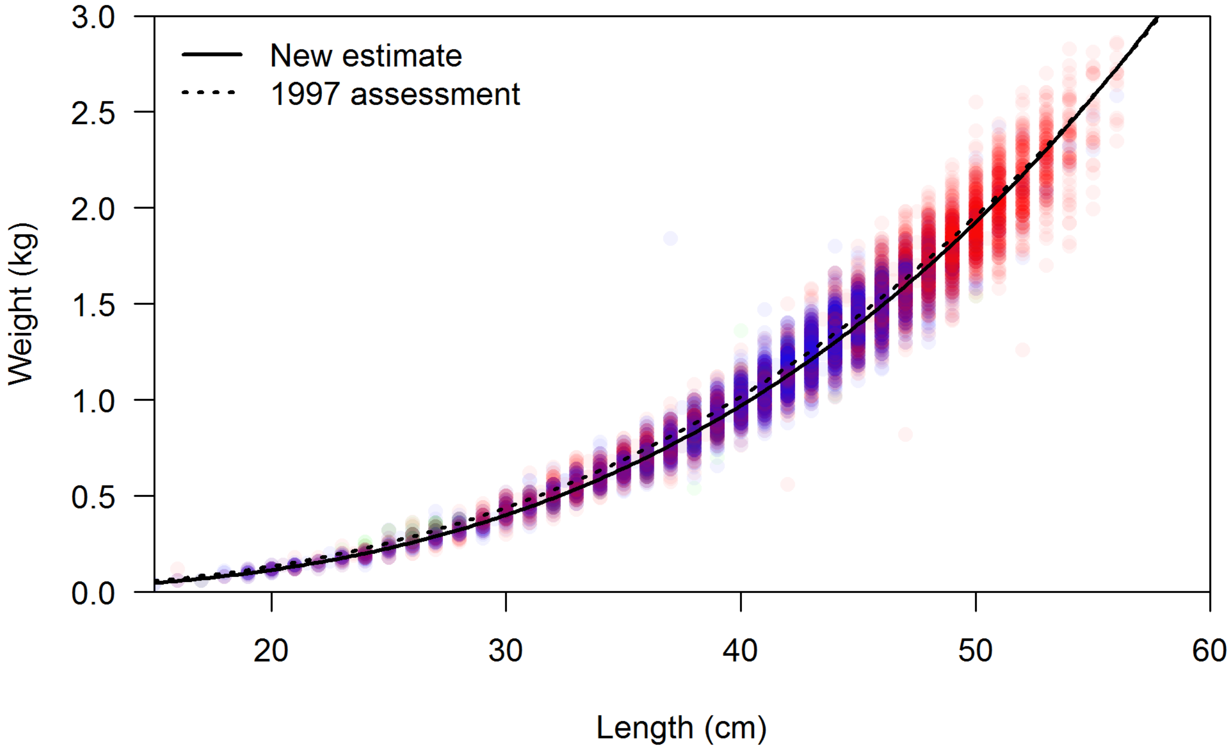

Figure 4: Estimated weight-length relationship for Yellowtail Rockfish used in both models. Colored points show observed values (red for females, blue for males, and green for unsexed). The black line indicates the estimated relationship $W = 0.000011843L^{3.0672}$. fig:weight-length

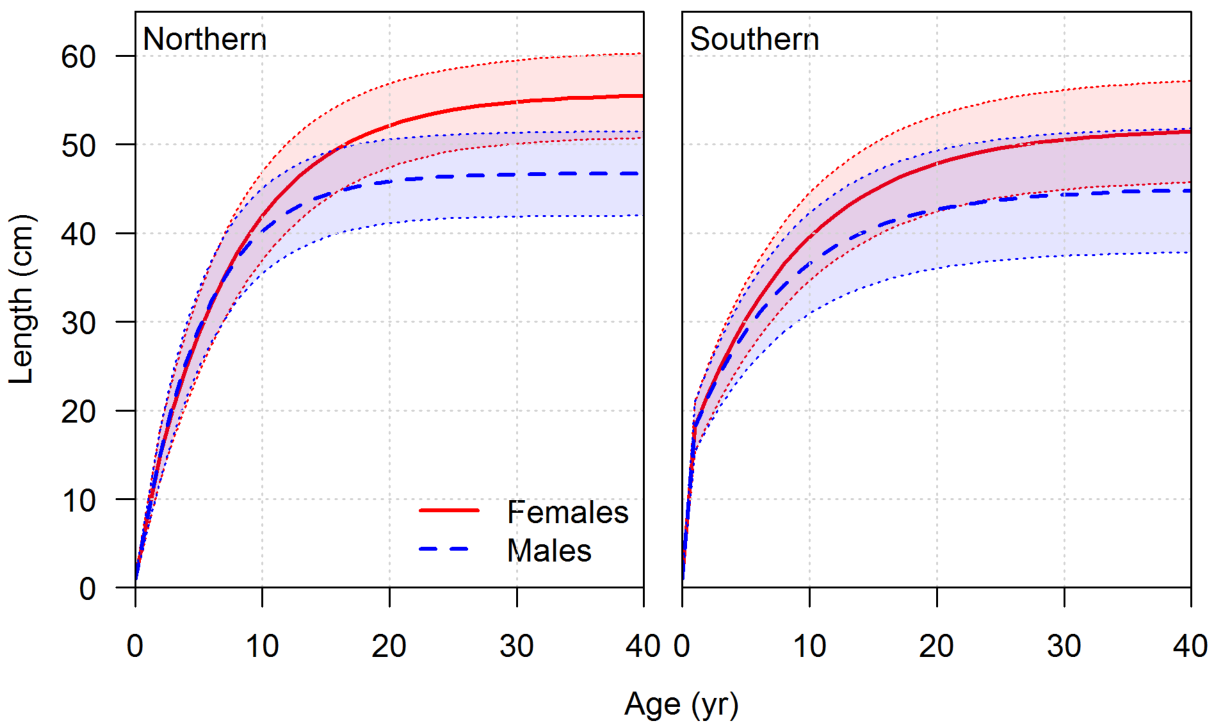

Figure 5: Estimated length-at-age for female and male Yellowtail Rockfish in each model. Shaded areas indicate 95% intervals for distribution of lengths at each age. Values represent beginning-of-year growth. fig:growth

1106 ## 9.2 Data and model fits for the Northern model

data-and-model-fits-for-the-northern-model

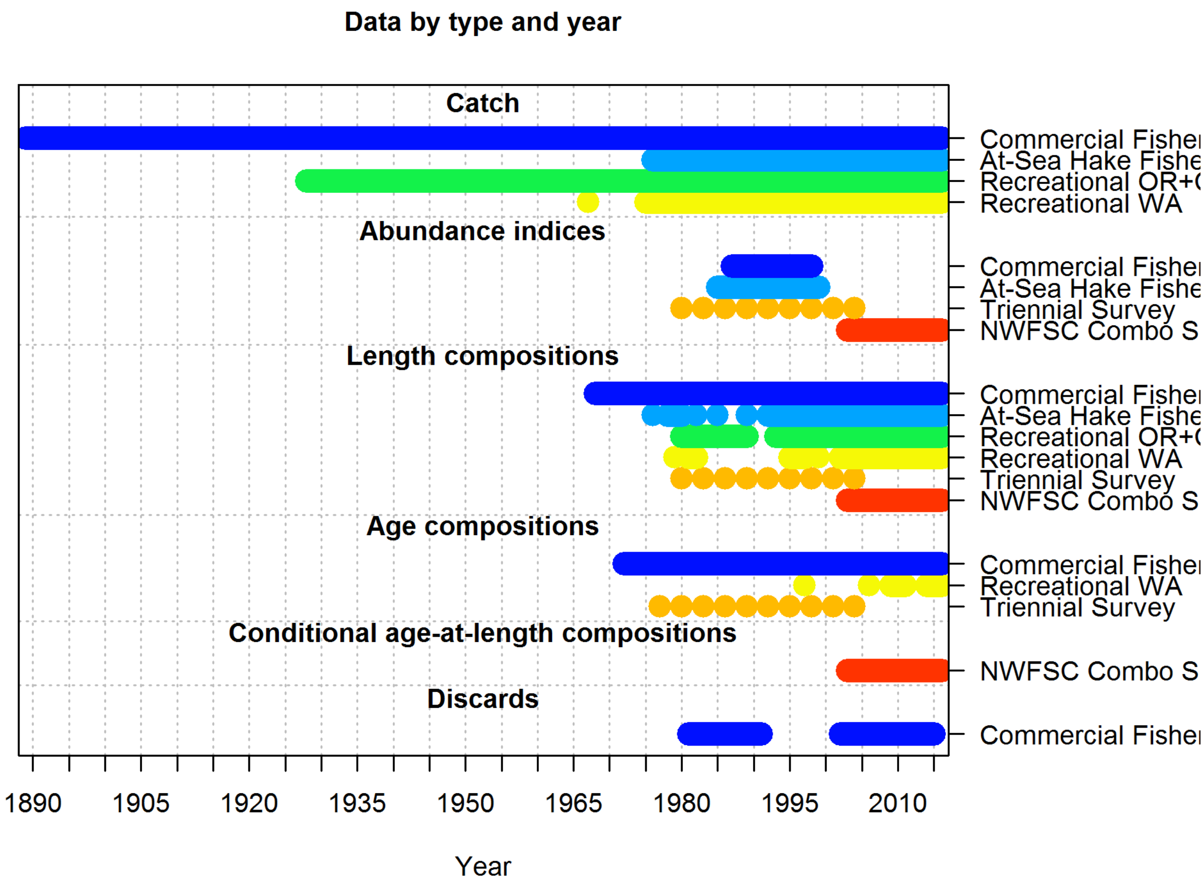

Figure 6: Summary of data sources used in the Northern model. fig:data_plot

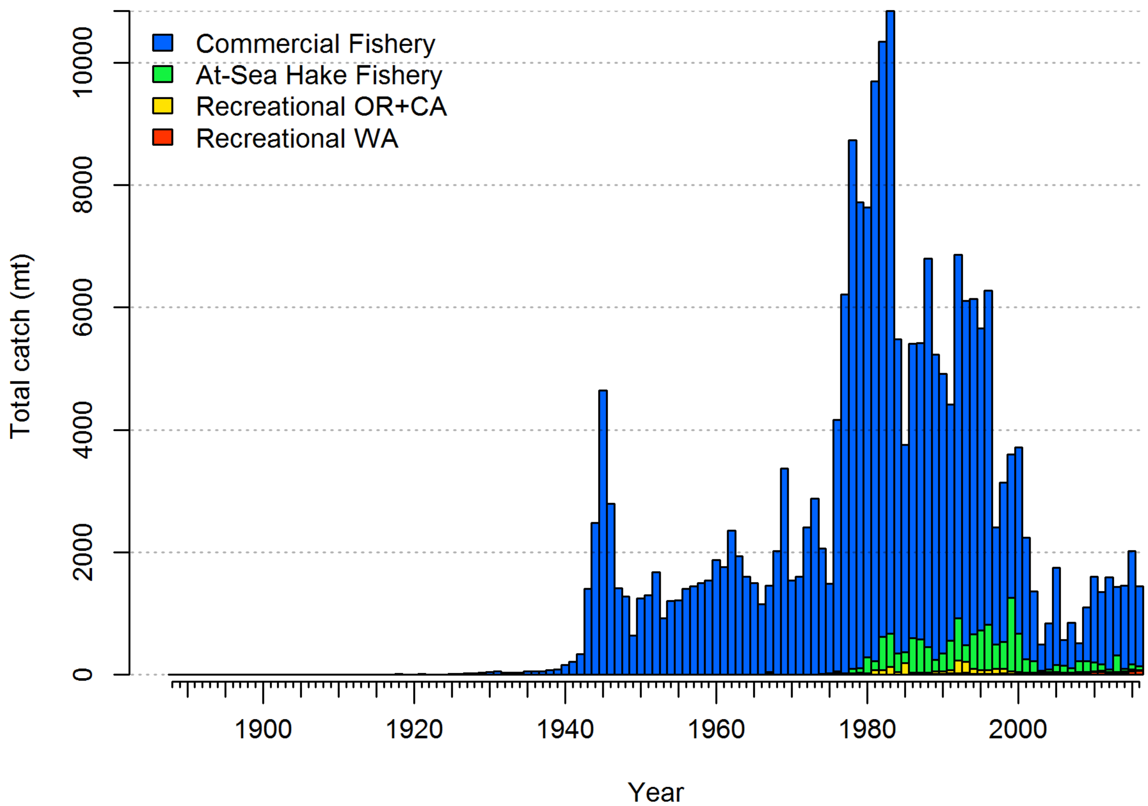

Figure 7: Estimated catch history of Yellowtail Rockfish in the Northern model. Recreational catches in Washington are model estimates of total weigth converted from input catch in numbers using model estimates of growth and selectivity. Catches for the Commercial Fishery include estimated discards. fig:r4ss_total_catch_N

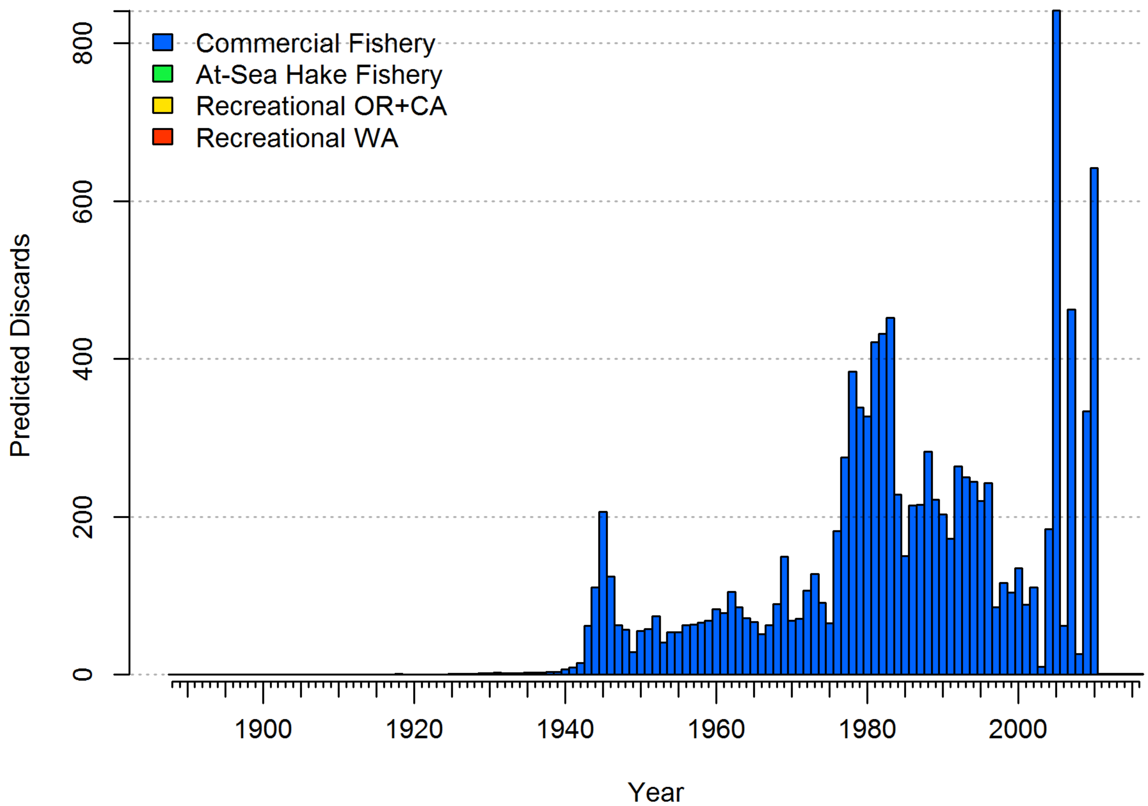

Figure 8: Estimated discards in the Commercial Fishery in the Northern model. Estimates are influenced by the data for landings, discard ratios, and discard length combines and depend on the estimated parameters controlling selectivity and retention. fig:r4ss_discard_N

1107 ### 9.2.1 Selectivity, retention, and discards for Northern model

selectivity-retention-and-discards-for-northern-model

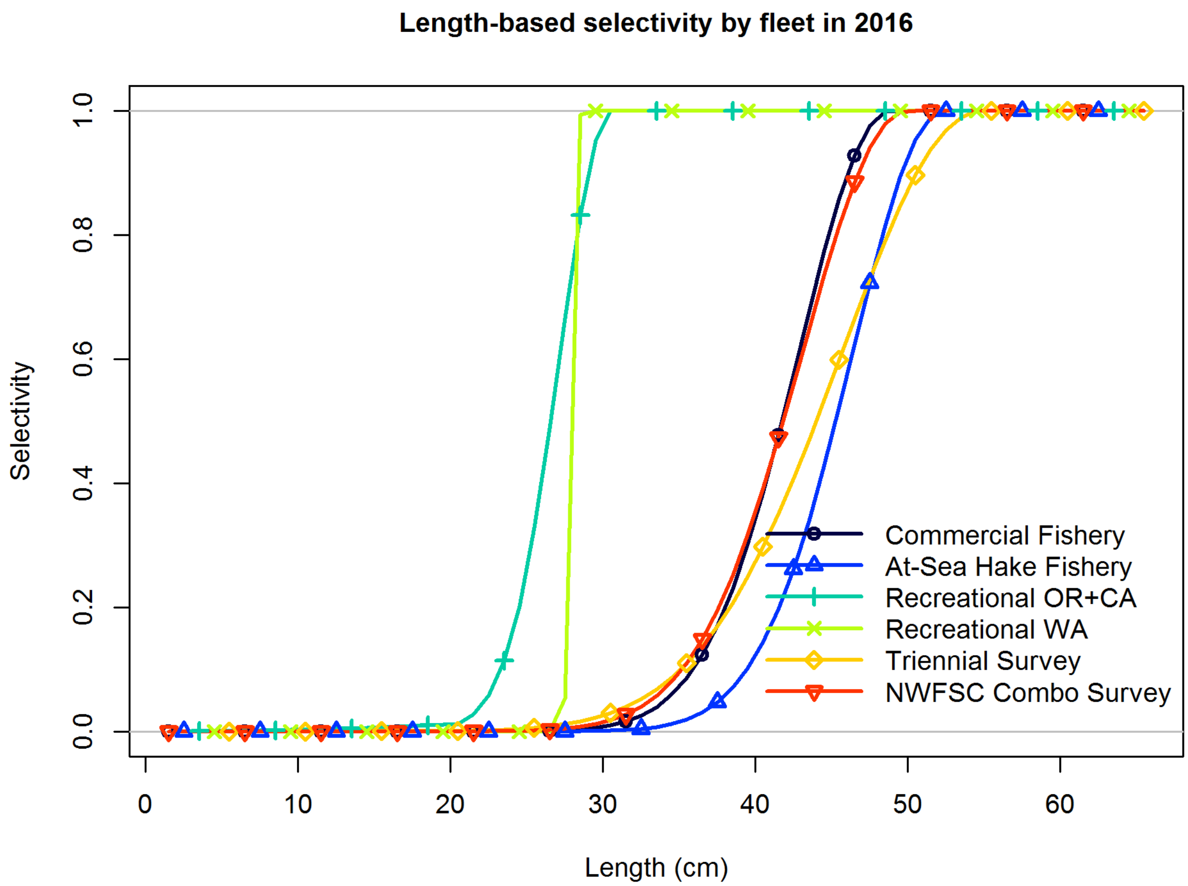

Figure 9: Estimated selectivity by length by each fishery and survey in the Northern model. fig:selex

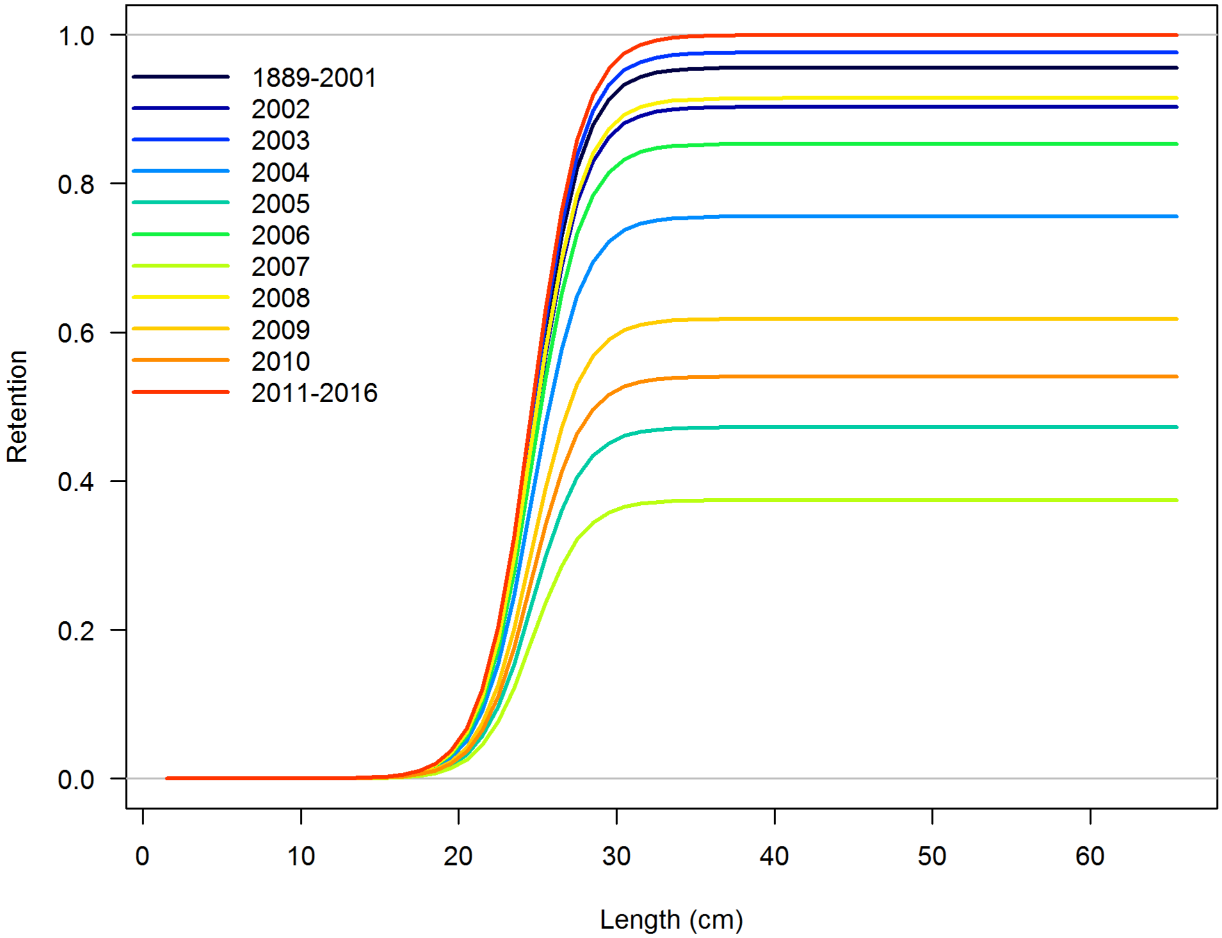

Figure 10: Estimated retention by length by the Commercial Fishery in the Northern model. fig:retention

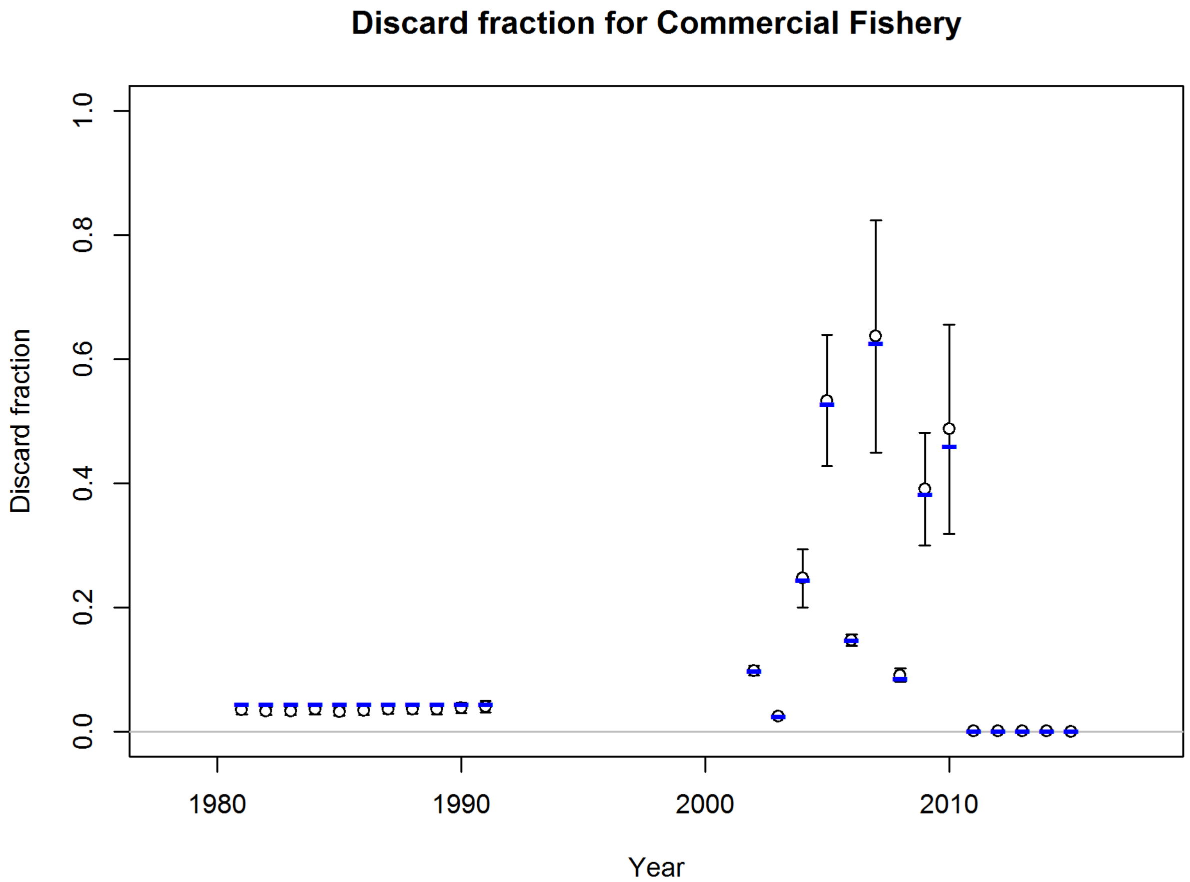

Figure 11: Fit to discard fractions for the commercial fishery in the Northern model. fig:r4ss_discard

9.2.2 At-Sea Hake Bycatch Index

at-sea-hake-bycatch-index

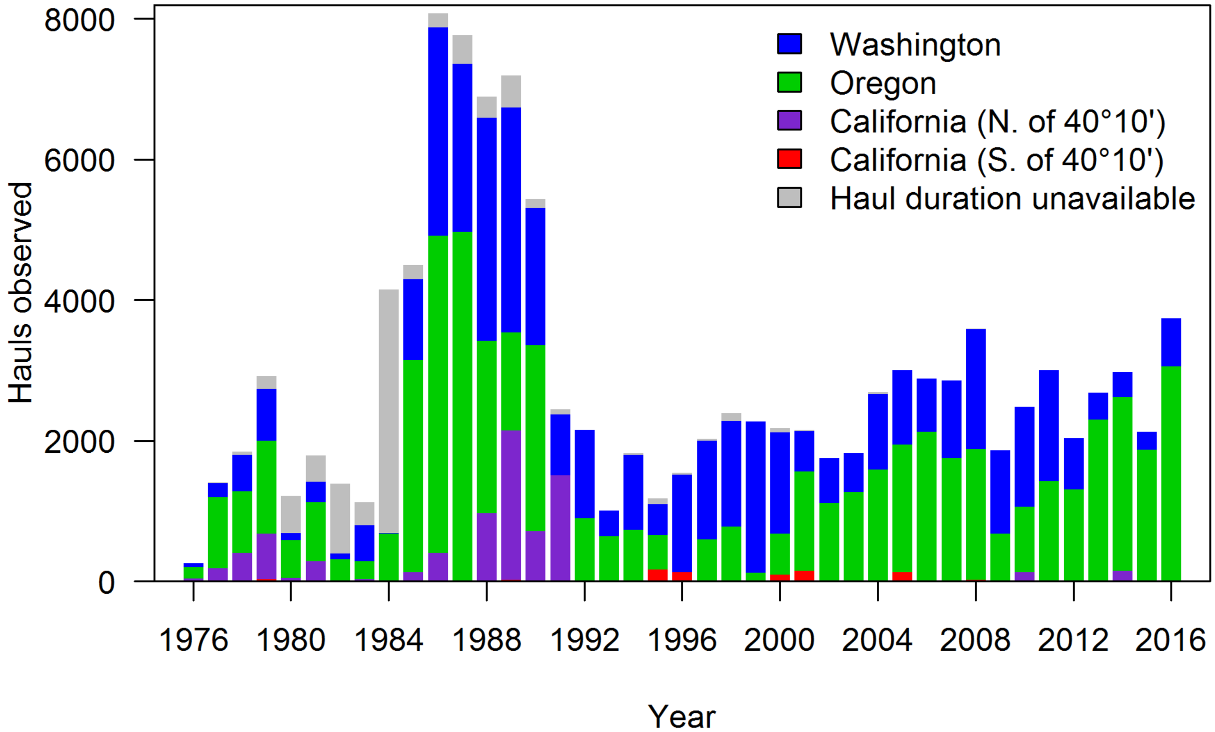

Figure 12: Number of observed hauls from the at-sea hake fishery classified by location relative to Washington, Oregon, and California (north and south of 40-10). Grey bars indicate observed tows with no haul duration available which were excluded from the CPUE analysis. fig:ASHOP_X1

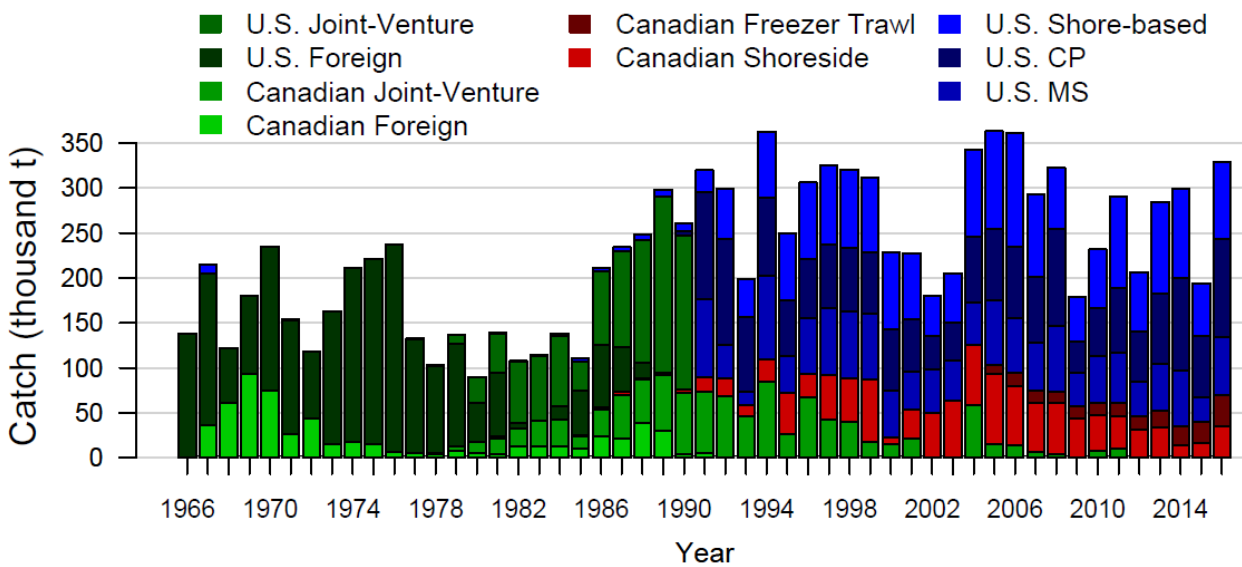

Figure 13: Catch history for Pacific Hake by sector. Data used in the CPUE analysis are from the "U.S. Joint-Venture" and "U.S. Foreign sectors" through 1990 and from the Catcher-Processor ("U.S. CP") and Mothership ("U.S. MS") sectors from 1990 onward. fig:ASHOP_X2

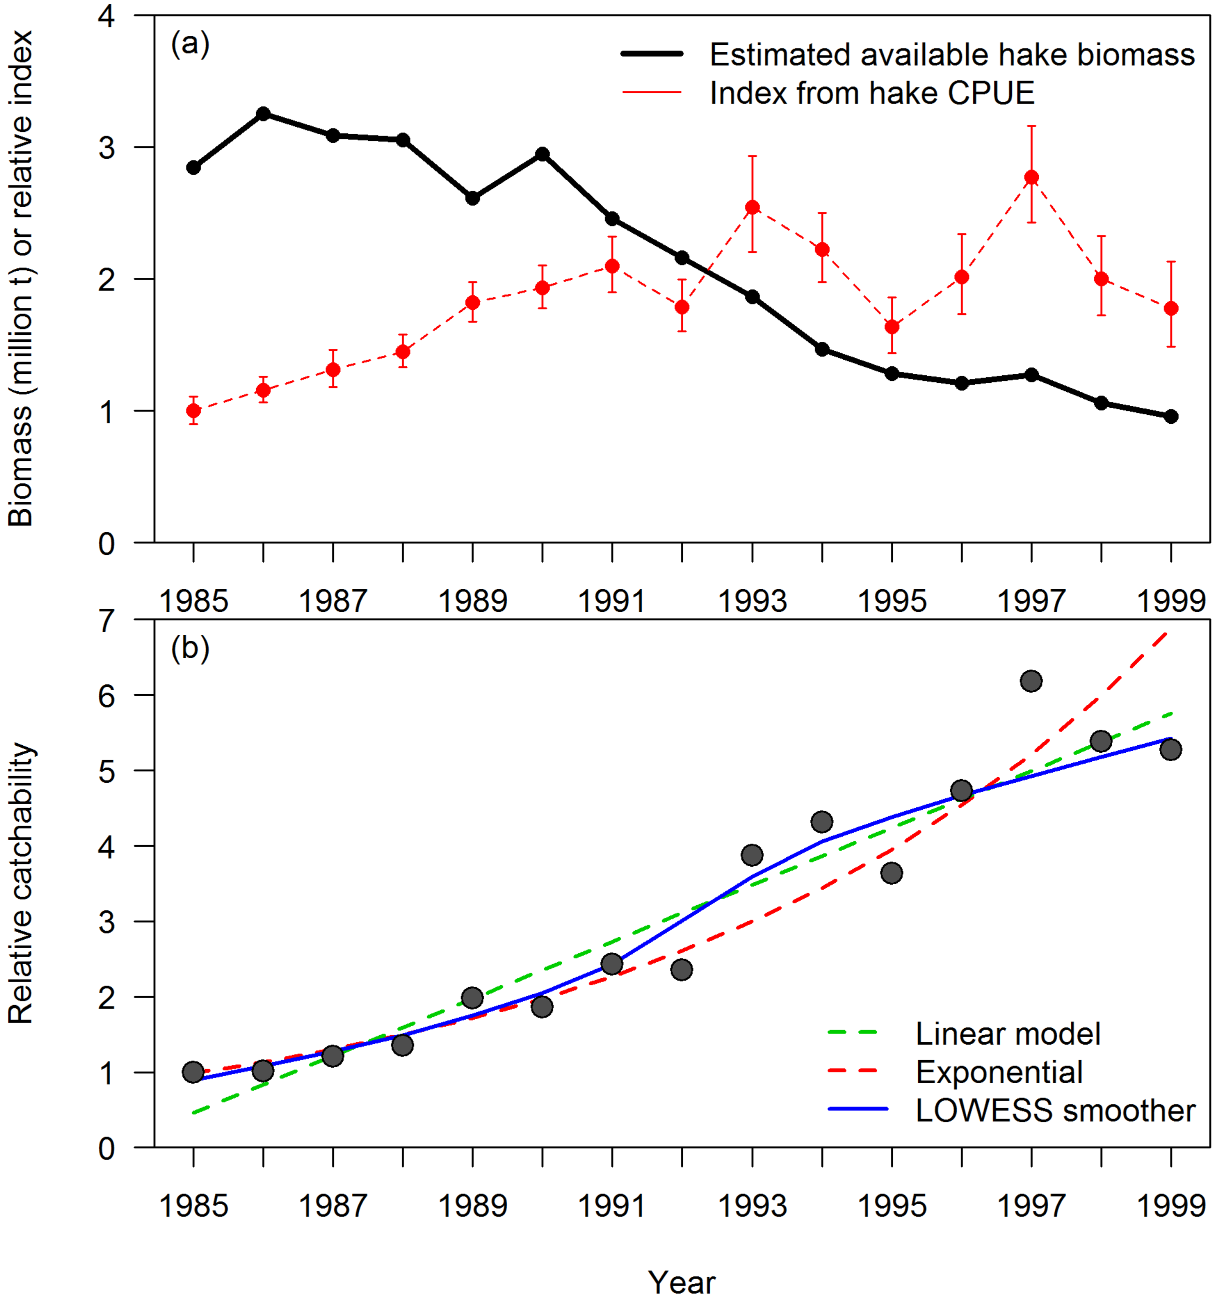

Figure 14: Geostatical index for Pacific Hake developed using VAST compared to the estimated avaialble hake biomass. fig:ASHOP_X3

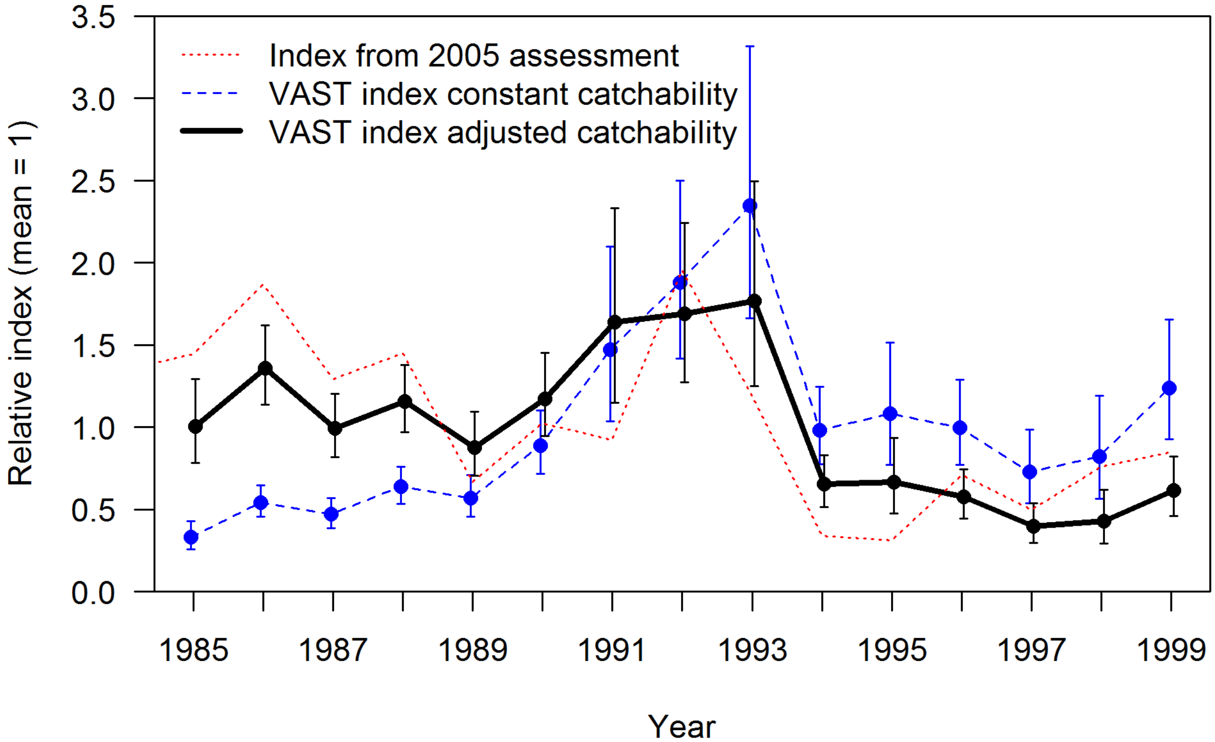

Figure 15: Index from the geostatistical model VAST with constant catchability and adjusted for the estimated increase in catchability (previous figure). These are compared to the index from the most recent yellowtail assessment (Wallace and Lai, 2005). fig:ASHOP_X4

1109 ### 9.2.3 Fits to indices of abundance for Northern model

fits-to-indices-of-abundance-for-northern-model

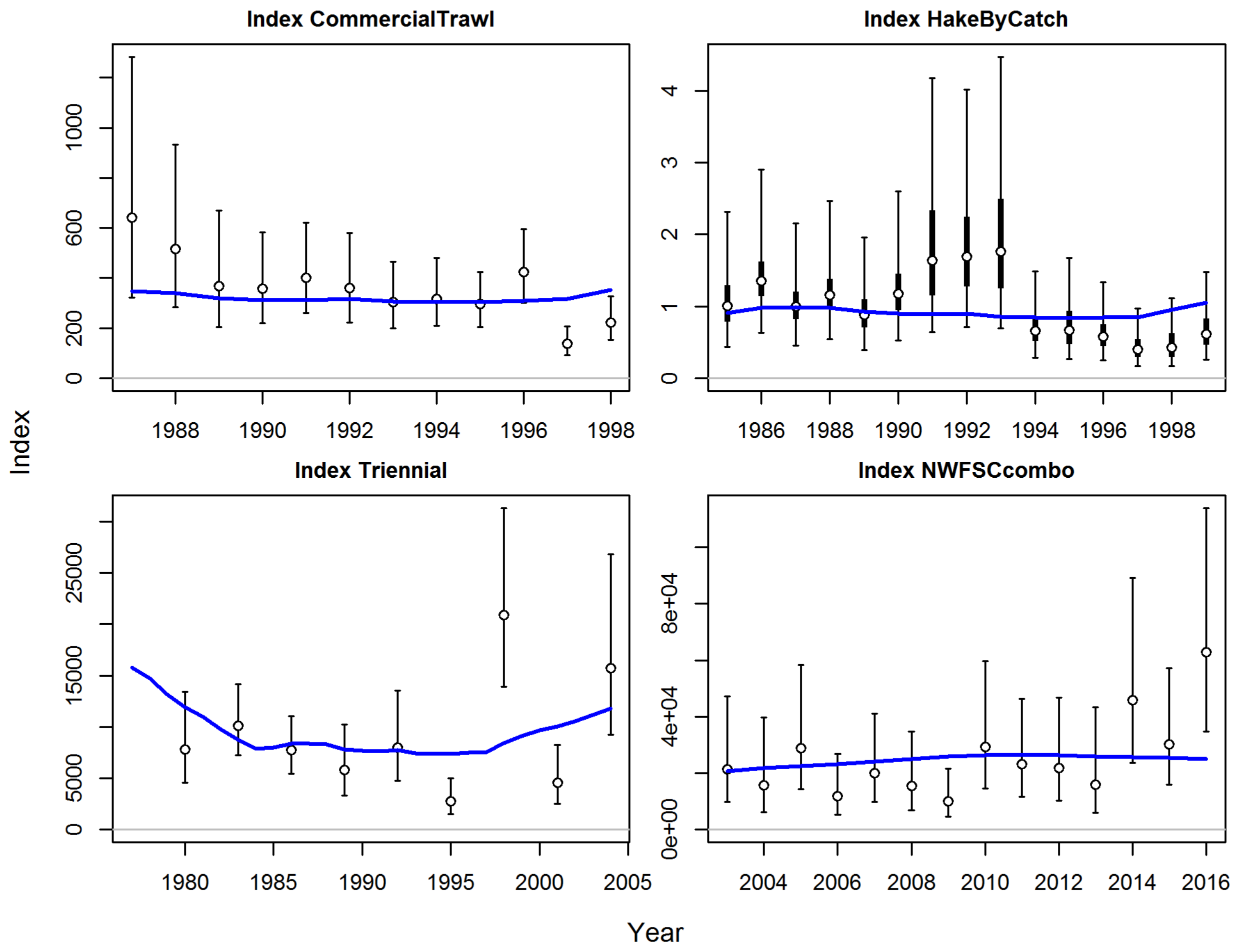

Figure 16: Estimated fits to the CPUE and survey indices for the Northern model. fig:index_fits1

9.2.4 Length compositions for Northern model

length-compositions-for-northern-model

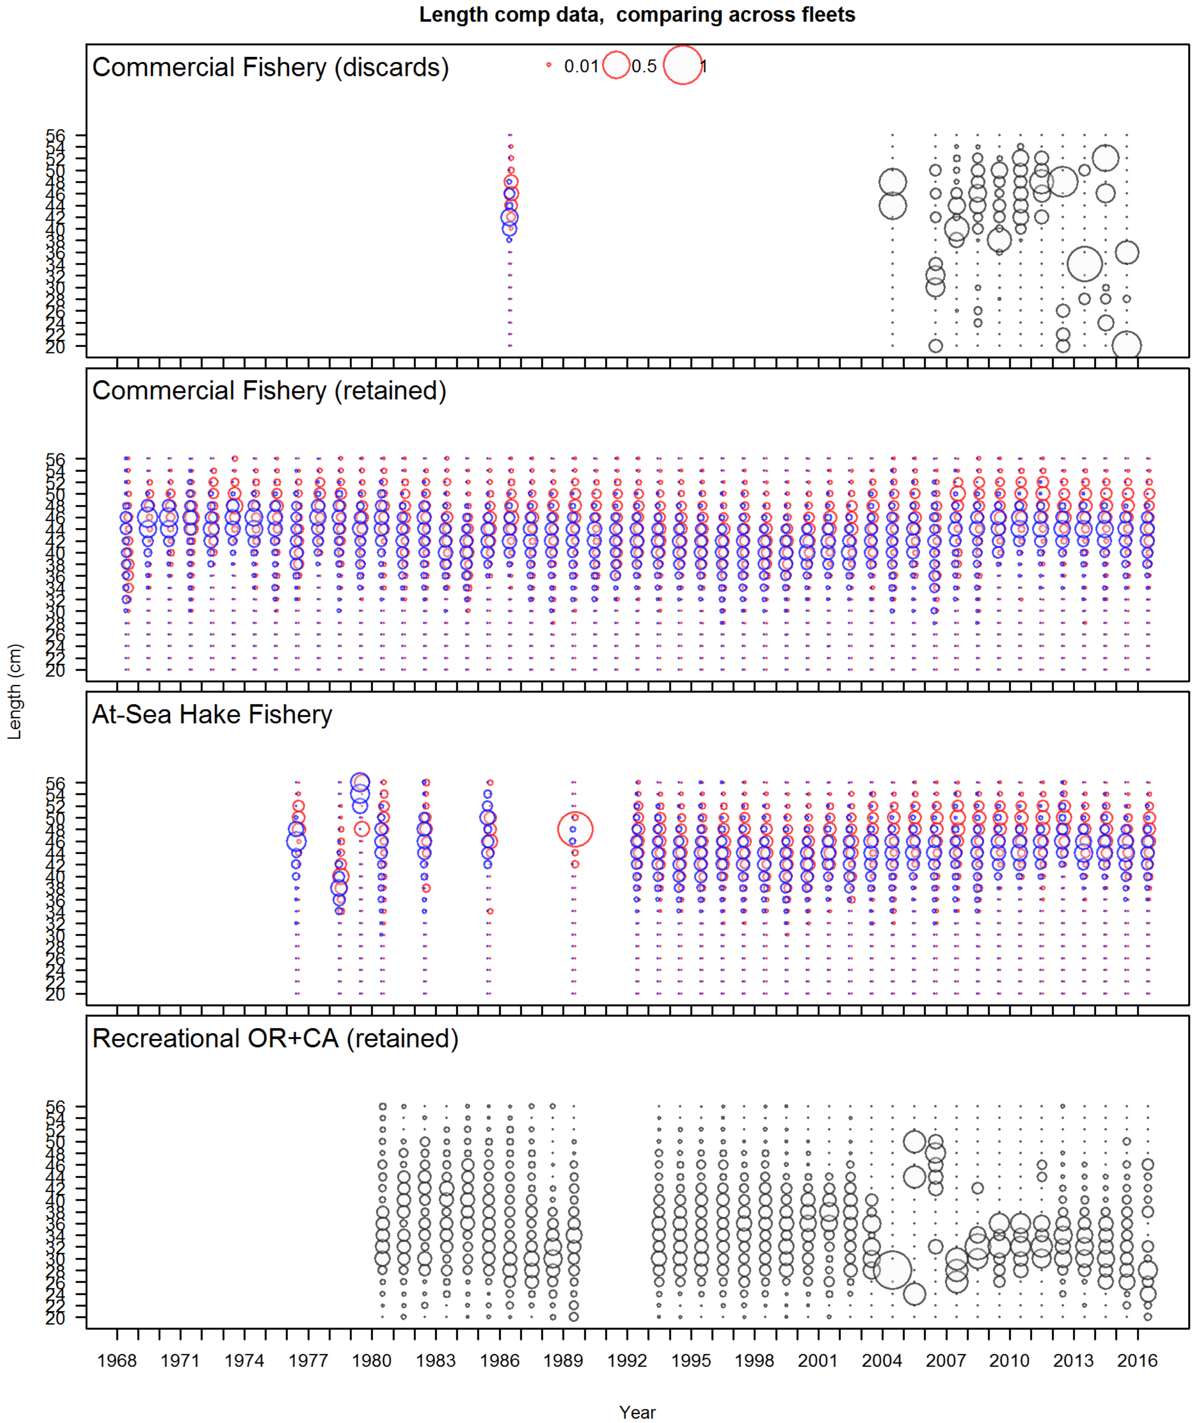

Figure 17: Length compositions for all fleets in the Northern model (figure 1 of 2). Bubble size is proportional to proportions within each year. Bubble colors indicate unsexed fish (gray), females (red), and males (blue).fig:comp_length_bubble_mod1_page1

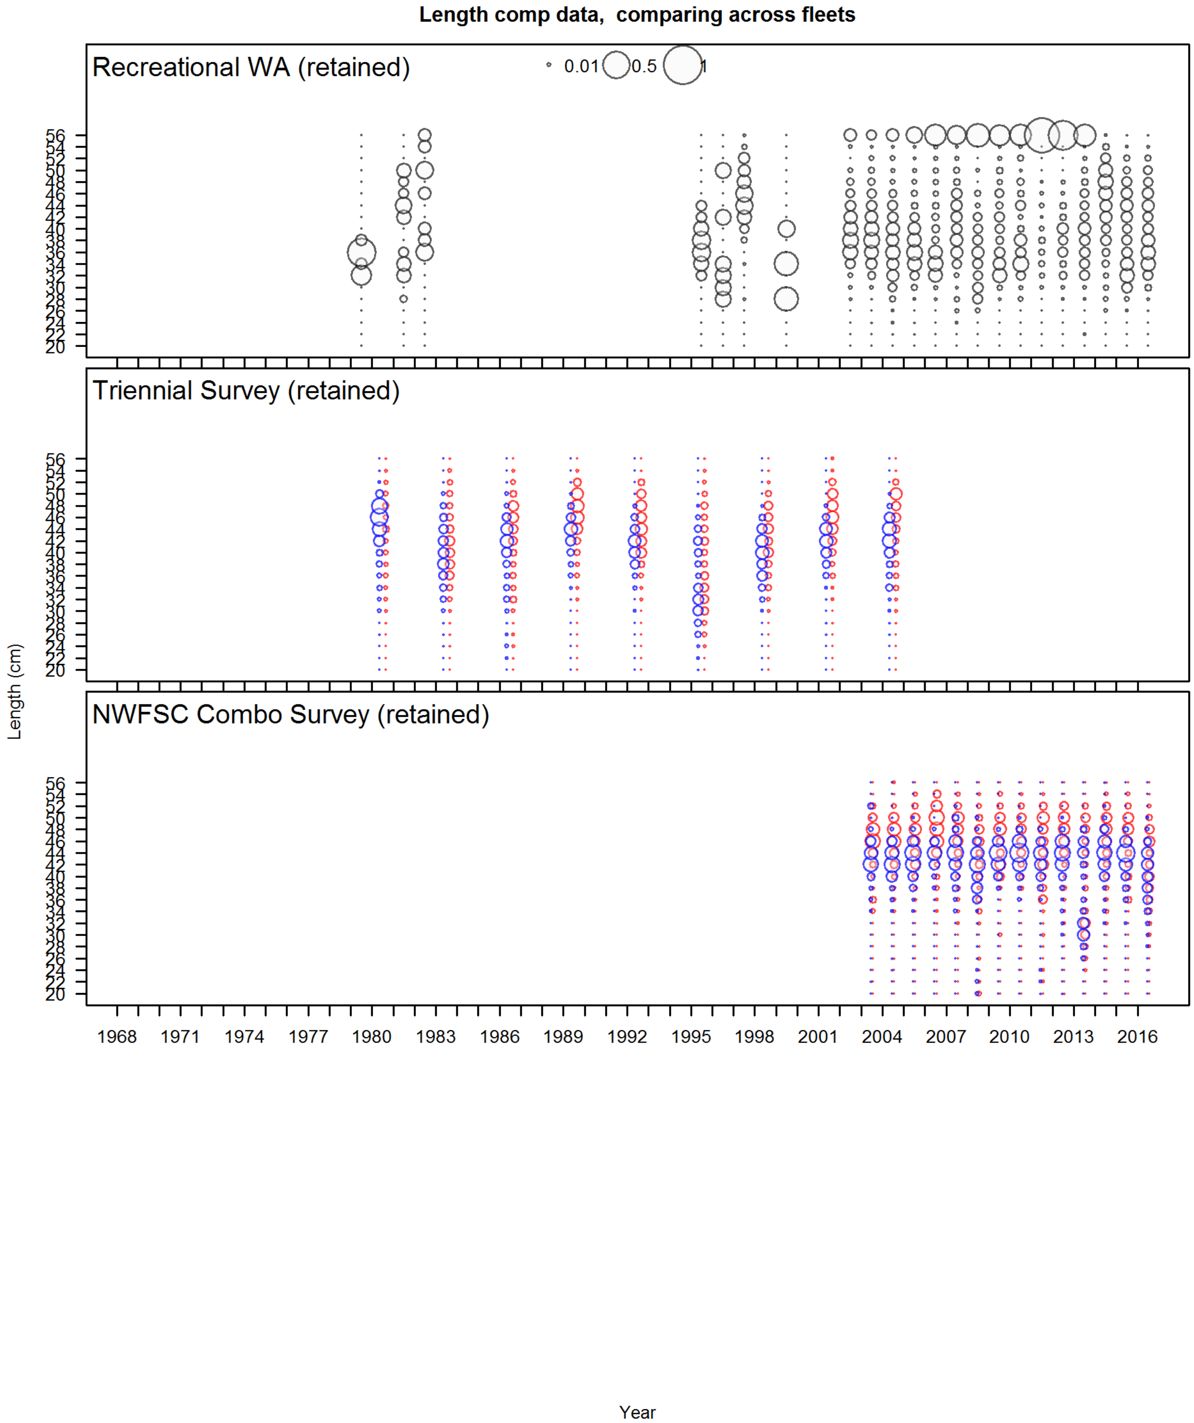

Figure 18: Length compositions for all fleets in the Northern model (figure 2 of 2). fig:comp_length_

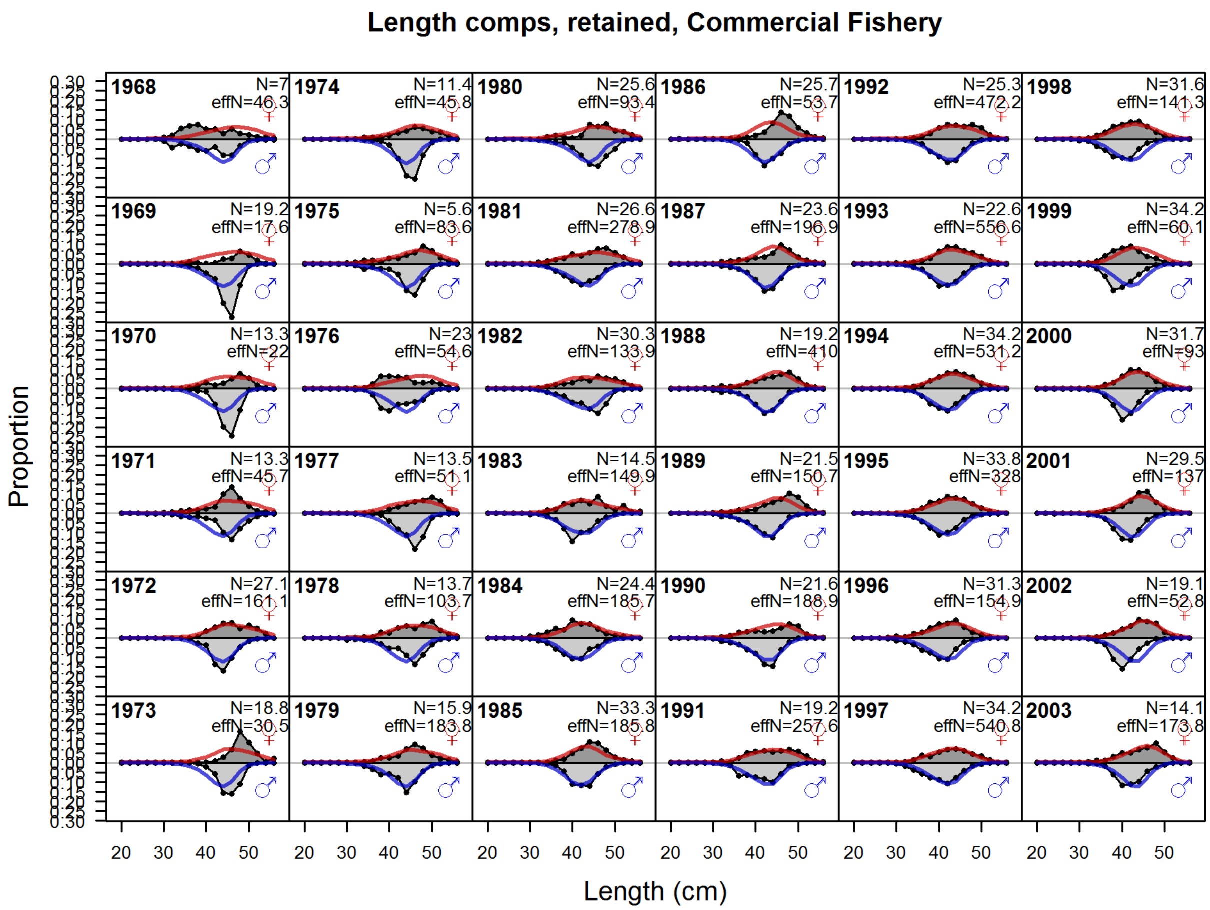

Figure 19: **Northern model** Length comps, retained, Commercial Fishery (plot 1 of 2) fig:mod1_1_com

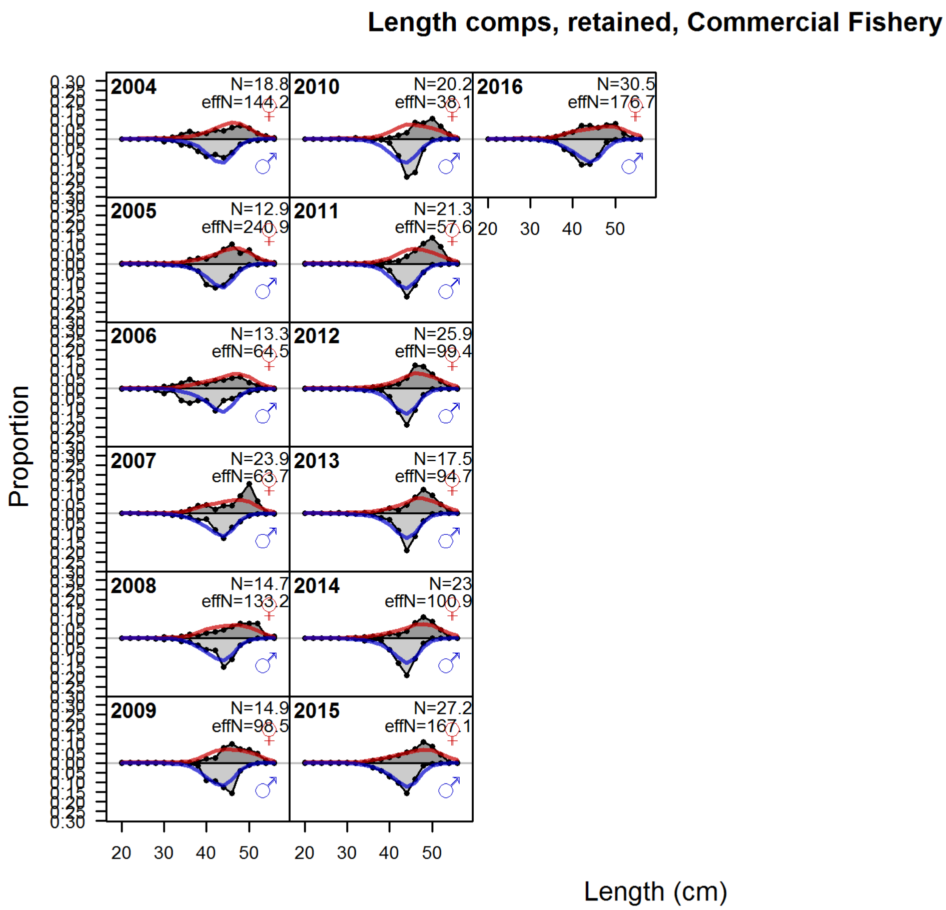

1111

1112 Figure continued from previous page

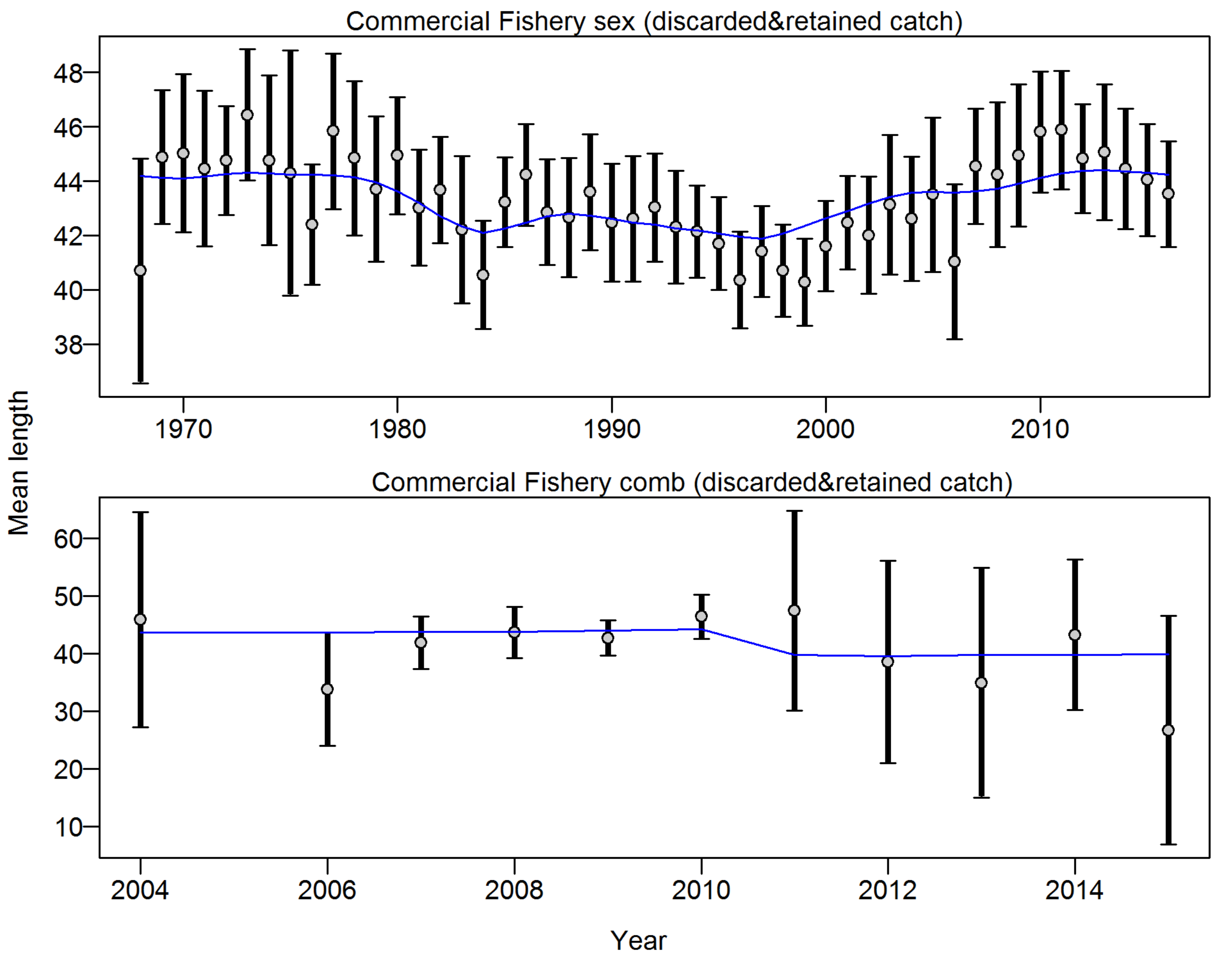

Figure 20: **Northern model** Mean length for Commercial Fishery with 95% confidence intervals based on current samples sizes. Francis data weighting method TA1.8: thinner intervals (with capped ends) show result of further adjusting sample sizes based on suggested multiplier (with 95% interval) for len data from Commercial Fishery: 0.9821 (0.7428_1.4551) For more info, see Francis, R.I.C.C. (2011). Data weighting in statistical fisheries stock assessment models. Can. J. Fish. Aquat. Sci. 68: 1124_1138. fig:mod1_5_comp_lenfit_data_weighting_T

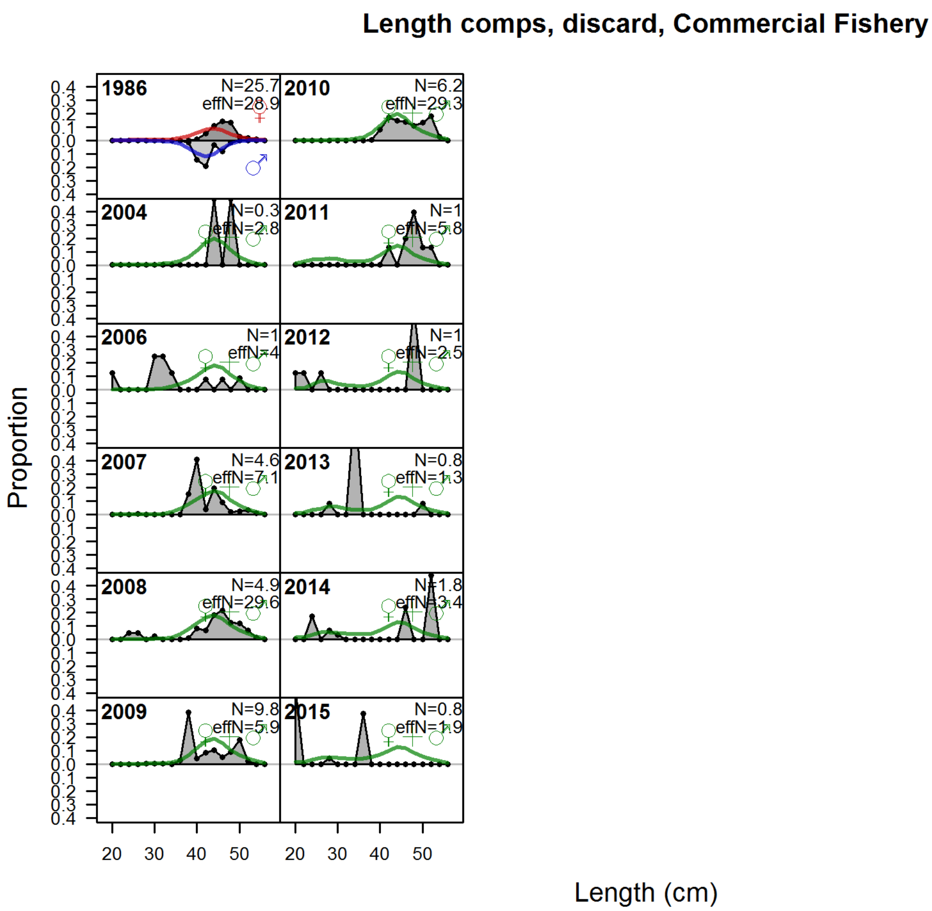

Figure 21: **Northern model** Length comps, discard, Commercial Fishery fig:mod1_6_comp_lenf

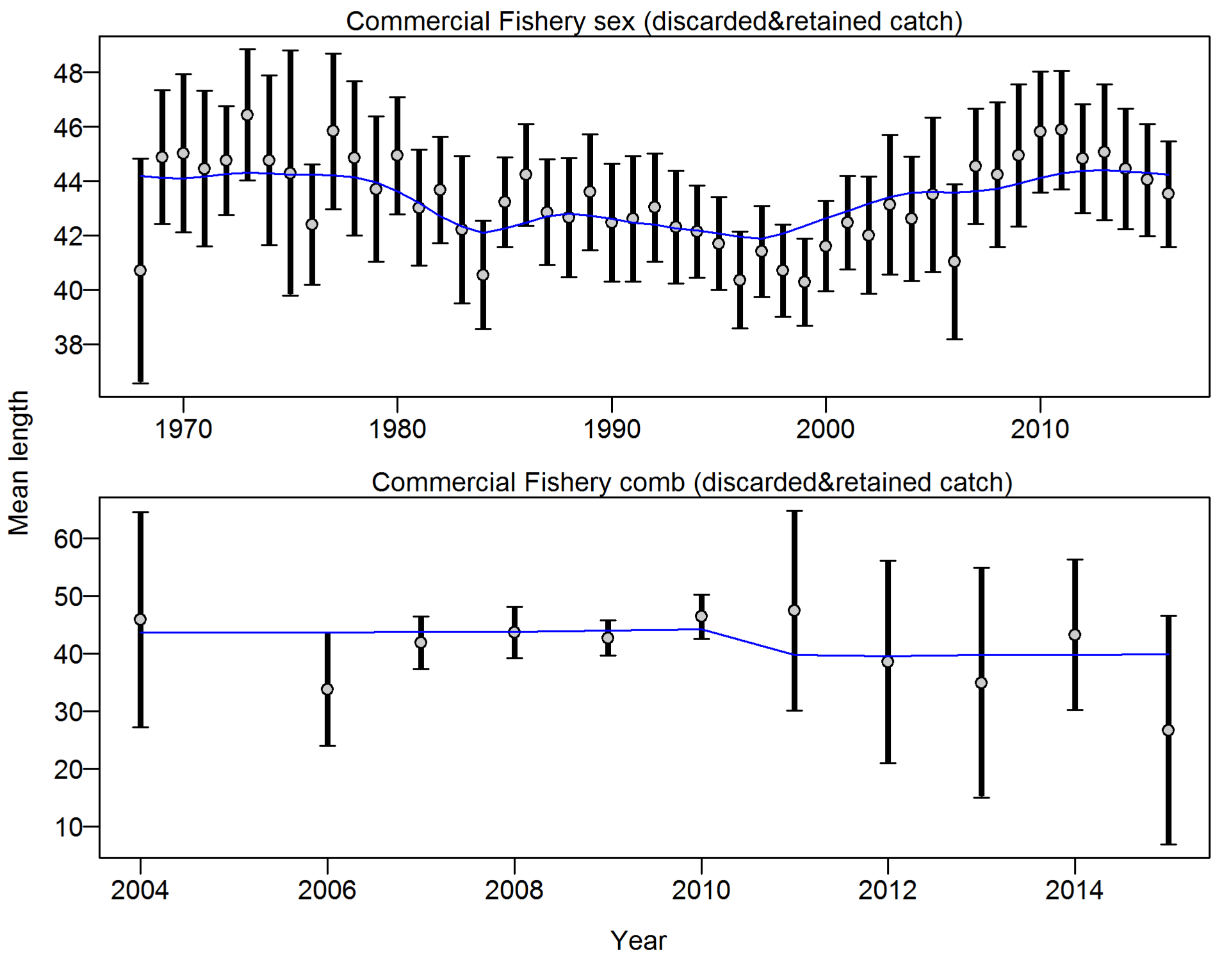

Figure 22: **Northern model** Mean length for Commercial Fishery with 95% confidence intervals based on current samples sizes.
